FOREWORD

Need for harnessing natural resources to the advantage of society requires no special mention. The burgeoning demand for energy imposes severe strain on conventional energy resources and causes adverse environmental impacts due to climate change, acid deposition etc. Both the carbon and hydroelectric pathways to conventional power generation are, therefore, not sustainable in the long run. The other major source i.e. nuclear power, has its own set of environmental risks and waste disposal problems. Renewable energy like solar radiation, wind, ocean waves etc. are free from these limitations but are hitherto untapped in any major way. The Government of India in its National Action Plan on Climate Change, has decided to launch an ambitious Solar Mission.

Assessment of solar energy potential across different geographical regions requires long-term measurements from a well-calibrated network of stations, like the one maintained by IMD since 1957. In 1981 a report was prepared by Miss A. Mani and subsequently published as a monograph edition named "Handbook on Solar radiation data over India". It has been widely used by engineers and energy policy makers. An update on this report has become overdue in view of climatological changes during the last 3 decades. The present publication – "Solar Radiant Energy over India" proposes to fill this gap and also to provide data on numerous other parameters such as atmospheric transparency – representing effect of aerosols, long wave radiation from the ground and atmosphere and estimation of radiation from INSAT data. This makes the publication comprehensive and relevant to a large range of solar energy issues.

The presentation of the data is lucid and is supported by explanatory notes. The data has been collected at hourly intervals, which is of immense value in solar energy applications. Moreover, it is also available in soft version enabling the data to be directly analyzed by computers.

I feel that the present publication will be extremely useful to entrepreneurs as well as research workers. I recommend this book for wide and practical use.

(PRITHVIRAJ CHAVAN)
Minister of State(IC) for
Science & Technology and
Earth Sciences

FOREWORD

The book on 'Solar Radiant Energy over India' meets the long felt requirement of solar energy users in India. The data pertaining to solar radiant energy available in this book, will be of immense help to the designers of solar energy power systems. This publication has been brought out at such a time when the whole world and India is in deep energy crisis due to rising prices of crude oil. Alternate sources of energy like solar energy available in abundance in India is required to be harnessed to an optimal level and this book will be a source of valuable information to the users.

This work was financed by the Ministry of New and Renewable Energy and carried out at the Radiation Laboratory, Office of the Dy. Director General of Meteorology (Surface Instruments), India Meteorological Department, Pune. The work involved collection and analysis of huge amount of radiation and meteorological data from 1986 to 2000 for 23 field stations of radiation network of India Meteorological Department; hence took longer time than anticipated. However, the efforts made by Shri V. Desikan with the active support of other members of editorial board and officers and staff in the office of DDGM(SI) have succeeded in completing this task under the proficient and constant guidance of Dr. R.D. Vashistha, Dy. DGM(SI). The major part of the data which forms the basis for the book was collected from the national network of radiation stations operated by the India Meteorological Department and were made available by the National Data Centre of the India Meteorological Department at Pune. A similar work entitled 'Handbook of Solar Radiation Data' was earlier completed by A. Mani (1980) using radiation data of 18 stations that used data up to 1978. The atmospheric conditions have changed significantly during the course of time due to rapid industrialisation and urbanisation, making it inevitable to update the information.

I would like to congratulate the members of the editorial board and the Director General of Meteorology Dr. Ajit Tyagi, Editor-in-Chief of the Book, for bringing out such an excellent publication of practical use to the scientists and technologists.

Shailesh Nayak
Secretary
Ministry of Earth Sciences

Contents

Preface		ii
Chapter I	Introduction	1
Chapter II	Measurement of Radiation Parameters	20
Chapter III	Network of Radiation stations	73
Chapter IV	Data Management	82
Chapter V	Radiation Climatology of India	95
Chapter VI	Representative Meteorological Year	116
Chapter VII	Connected Algorithms	122
Chapter VIII	Features of Indian Climatology	163
Appendix 1	Diagrams – Analyses of radiation data	193
Appendix 2	Tables – Mean monthly distribution of various Parameters	270
Appendix 3	Tables – Daily values for a representative year for each station.- Data available on CD only	
Appendix 4	Climatological data for each station.	831

Preface

The resources for generating power by conventional methods by exploiting coal, petroleum and water are fast depleting and there is every possibility of energy starvation to occur in many places. Besides, the pollutants added to the environment by these methods (except by hydroelectric process) have already made the ecological balance nearly fragile. Thus there is an urgent need for the entire humanity to tap other resources which will at the same time be ecologically friendly. Some of such resources (non-conventional) are the sun, the wind, the sea waves and geothermal sources. The nuclear power resources do provide a very large potential but the attended hazards like irradiation, disposal of radio active wastes, radioactive contaminations and attended accidents have catastrophical consequences. Among the non-conventional resources, the energy from the sun is a primary one, unbounded by territorial or monopoly limitations. While this is applicable to wind as well, the problem with wind is that it is not strong enough throughout a year at a given place to ensure consistent energy conversion. The solar energy received by the earth is more than 15,000 times the world's commercial energy consumption and over 100 times the world's known coal, gas and oil reserves. And this energy is readily available during the day for anyone to tap and that too free and without any constraint.

There are, however, some other limitations for this energy source. Clouds happen to impose the most important limitation. Added to this factor, the particulate matter and the radiatively active gaseous matter present in the atmosphere alter the quantity of radiant energy reaching the earth's surface. In addition to taking preventive measures to reduce the attenuating agents in the atmosphere, it is necessary to have an idea on the atmospheric transparency to the incident solar energy and the periods when this energy can be viably useful. Since inter-annual variability in the atmospheric conditions can be very large, it is essential to obtain the necessary data inputs for tapping the energy efficiently. Also, the geographical and astronomical variations are imposed on this energy resource. There are evidently spatial inhomogeneities in the distribution of solar energy over a large area. Thus for a large country like India, it is of utmost importance to have a reasonably well planned network representative of various regions, so that the distribution of the various components of the solar energy can be properly estimated and the data thereon made available for various disciplines of users.

To meet this requirement, India Meteorological Department (I.M.D.) is maintaining a network of radiation measuring stations in India. The network which initially had 4 stations in 1957 has gradually expanded to the present 40 odd stations. The most basic parameter, the incident solar radiant energy – directly and scattered – is measured at all the stations. The scattered component – diffuse solar irradiation – is measured at 24 locations in India. The department will shortly be embarking in augmenting and modernising the measurement schedule by introducing continuous monitoring of the very important terrestrial radiant energy and of the biologically important ultraviolet irradiation. The data obtained at different sites spread over the country are collected by the Climatology Division of the Department at Pune and scrutinised thoroughly before being archived at the National (Climatological) Data Centre at Pune.

A. Mani (1980) and A. Mani and S. Rangarajan (1982) had brought out two volumes on solar energy. The first one is "Handbook of Solar Radiation Data for India" and the second is "Solar Radiation Over India". The first book contains the results of measured values. The second one gives the derived values – derived based on various meteorological parameters. The main purpose of these books is to provide a database for the designers of systems for harnessing the solar energy received at a place. The data contained there have been well received and widely utilised. A revision of the first volume was long overdue as the country has been undergoing large-scale developmental activities and these should have some adverse effect on the environment.

A core group of seven scientists was formed by the then Ministry of Non-Conventional Energy Sources on May 20, 2003 to examine the feasibility of updating the Handbook. After deliberations over two sittings, a project report was submitted on September 18, 2003. The revision of the Handbook of the report was approved on March 26, 2004 and was to be implemented through the aegis of India Meteorological Office, Pune and through the funding by the then Ministry of Non-Conventional Energy Source. The scope of the revised version has been enlarged to include various turbidity parameters, atmospheric transmission coefficients in different broad spectral ranges, the vertical profile of terrestrial radiant energy of the earth and the atmosphere. Also included are the outgoing terrestrial radiant energy as derived from satellite based measurements. Thus this version is to cater to the needs of not only the technologists but also the scientific research workers.

All stations do not use the same type of instruments and also do not have the same parameters to be monitored. 23 stations were identified which have a common database - those of global solar irradiation and of diffuse solar irradiation. The data period covered is from 1986 to 2000. Direct solar irradiances are measured at 21 locations - 13 making instantaneous observations at selected timings during the daytime and 10 others record it continuously with the sensors on solar trackers. Surface-based terrestrial radiant energy is monitored at 12 locations. The important net total radiant energy measured at only 5 stations are included in this book, as these measurements could not be carried out due to improper exposure conditions at other stations. Vertical profile of terrestrial radiant energy is also limited to 6 sites due to the involved logistic problems.

The members of the core group have been made the members of the editorial board. Due to administrative process, the editor-in-chief has been replaced by another scientist. The introductory Chapter I gives the basics of radiation and terminology used as per the requirement of international scientific terminology. Hence the more popular terminologies and the units are not given in this book. The different types of instruments that are used in radiation measurements with special thrust on those used in the Indian network are detailed in Chapter II. An account on the Indian network of radiation stations and on the Central Radiation Laboratory, Pune is given in Chapter III. Next chapter deals with the network maintenance standards and the traceability of the Indian data to international standards. Radiation climatology with a number of diagrams and tables forms Chapter V and Chapter VI is on data for a typical meteorological year which may give a representative picture of the values of various parameters for one year for a specific station. The various mathematical relations used in this work as well as several empirical relations that can be used to derive few of the radiation parameters make up Chapter VII. It is felt that the user of this book

should have a general idea on the different climatic conditions of India and these are given in Chapter VIII.

The work of revised version of A. Mani's Handbook was carried out as a project funded by the then Ministry of Non-Conventional Energy Sources. The data both radiation and meteorological were made available for the work from the archives of India Meteorological Department by the National Data Centre (NDC) at Pune. Whatever data that were archived and stored were supplied within a very short notice and in the least time possible. Shri Prakash Rao, Director, NDC and his colleagues Dr. Krishnakumar, Shri Joshi and Shri Padhye need to be specially mentioned for their ready cooperation and assistance in providing the data. The satellite based data on extra terrestrial net terrestrial radiant energy over the Indian region was provided by NDC and the Satellite Meteorology Division at IMD's headquarters in New Delhi. The radiation scrutiny unit provided access to the raw tabulations which were not yet computerised.

The analyses of data were carried out in the Central Radiation Laboratory, Instruments Division, Pune under the expert guidance of Shri V.Desikan who acted as a consultant in this project. Shri Desikan was involved in every stage of the preparation of the book – from planning the layout to the finalisation of the draft text. Shri. R.C. Bhatia provided the draft text on satellite based radiometric measurements. The members of the Laboratory extended all their cooperation and carried out the analyses involved despite their heavy work. Shri. P. Sunil and Shri. P.D. Kokate took care of software connected with analyses. Special mention, however, has to be made about the cooperation and speedy execution of all computations carried out by Shri. P.D. Kokate; but for his association, this project could not have come to its culmination. Shri. A.V. Mahajan extended his helping hand in working out the difficult typical meteorological year from the raw data provided to him. He had developed his own software for the purpose and worked out the weighting factors needed for the purpose. Shri. S.M. Perumal, Shri. R.B. Pataskar, Shri. S.R. Hanmante, Shri. R.J.Godse and Smt. S.P. Bhagwat provided all help in ensuring speedy collection of data which were not in computer format and formatting the final tables. Smt. S.V. Prabhu not only carried out corrections and scrutiny of the draft texts but did all editing needed in the preparation of every diagram. All this could be made possible by the constant encouragement and assistance so readily extended by Shri. R.K. Sharma, Director, Central Radiation Laboratory.

Special mention has to be made on the excellent support received from Dr. R. Vijaykumar, Scientist F (since retired) in the Indian Institute of Tropical Meteorology, Pune.

He readily shared his expertise in computer graphics. He spent quite a time in getting a series of diagrams (about 150 in all) in different appropriate colour codes that enhance the easy comprehension of the data and their distribution at a place or over the country. The assistance received from him is acknowledged with thanks.

Kum S. Belhe did all the works involved in putting the drafts in the computer format with excellent assistance from Smt. S.V. Prabhu. Lastly and very importantly, Shri. M.K. Gupta and Dr. R.D. Vashistha also members of the Editorial Board extended all help and all facilities of the Instruments Division – Office of Dy. Director General of Meteorology (Surface Instruments), Pune, in preparing this revised version. Smt. Usha Sudhakaran ably carried out all editorial checks.

The publication unit of the office of Additional Director General of Meteorology (Research), Pune under the able leadership of Shri Phillipose has undertaken the publication responsibility and brought out this book in its present elegant form.

C h a p t e r - I

INTRODUCTION

CHAPTER – I

INTRODUCTION

The earth and its atmosphere, depend ultimately on the sun for its energy supply. The fossilisation of organic and inorganic (degradable) substances on the earth provides an indirect supply option for energy. The latent heat and sensible heat transfers involved in the change of state of water also contribute to the energy states. The radiant energy from the sun is absorbed by the earth and the atmosphere and is partially redeployed as emission in the infra-red wavelength region, which controls the entire activity of all living organisms. This radiant energy also becomes the primary cause for driving the atmospheric heat engine to operate and sustain the atmospheric circulations and the ocean currents. The energy exchanges triggered by the solar heating of the earth-atmosphere system govern the weather at any given place. These heat exchanges including the direct heating effects lead to the formation of biomass, wind resources, ocean thermal gradients and waves and other geothermal sources for generating power.

1.1 The Sun:

The sun is basically a young and an almost invariable magnetic star. It is a slowly rotating body of hot and highly condensed gases with a strongly variable temperature gradient. The core of the sun is assumed to be made of ionized hydrogen and helium nuclei at very high temperatures. The various parts of the sun exhibit different temperatures. Its period of rotation around its axis is 25.38 days. It has a mean density of 1409 Kg m^{-3} , with a surface gravity nearly 28 times stronger than that of the earth. Its radius and surface area are $6.96 \times 10^8 \text{ m}$ and $6.087 \times 10^{18} \text{ m}^2$, respectively.

A temperature level of the order of 10^6K is maintained at the core by the nuclear fusion processes. Outside of this core area is the photosphere which is seen from the earth as a flat bright disc. This is the main source of solar radiation. The apparently smooth disc as it looks, is not of uniform brightness and has many brighter and darker regions. The darker regions which are at around 4500K are called the sunspots. The brighter ones are made up of 35-40 per cent brighter granules and faculae. The average temperature of the photosphere is estimated to be about 5800K . Outside the photosphere lies a narrow reversing layer which is at a relatively lower temperature of about 5300K . This layer has various elements in excited state and consequently gives rise to Fraunhofer's absorption lines. Chromosphere which is red in colour is an extension of the reversing layer. Spectacular explosions occur in the chromosphere, called the solar flares, sending streams of highly ionized particles into space. These cause intense disturbances in the upper reaches of the earth's atmosphere. Beyond the chromosphere is the corona, a rarified gas layer extending outward for several solar diameters.

The sun emits radiation in the entire electromagnetic spectrum from gamma rays to radio waves. Because of its very mechanism of emission, the radiant energy is a combination of energy released by layers which are at different temperatures. Even the photosphere which is the main source of solar radiation does not have uniform temperature distribution. Thus the sun is not a black body by the strict definition of a black body. However, approximating sun's radiant energy to black body radiation is sufficiently close, that it is normal practice to treat the sun as a black body radiator. The effective temperature at which the radiant energy is assumed to escape the sun is about 5800K .

The earth revolves around the sun in an elliptical orbit with the sun at one of the foci. The distance between the sun and the earth, therefore, changes continually during its revolution around the sun in about 365 days. The average or the mean sun - earth distance is $149.6 \times 10^6\text{km}$. At its perihelion position when the earth is nearest to the sun on January 1, the distance of the earth is about 98.3 per cent of the mean distance. On the other hand, it is farthest on the aphelion position on July 2, which is about 101.7 per cent of the mean distance. Because of these variations in the sun earth distance, the radiant energy intercepted by the earth also varies by about ± 3 per cent of its normal energy value. The radiant energy falling on a unit area, termed irradiance, at normal incidence outside the earth's atmosphere at mean sun-earth distance is termed the solar constant (S_0). Thus value of the solar constant varies from day - to - day depending on the actual distance from the sun. The present accepted value of solar constant derived from space-based measurements is $1367 \pm 7 \text{ Wm}^{-2}$, the uncertainty in the measurements being about 0.3 per cent.

Interaction with the atmosphere:

The radiant energy that is incident on the top of the atmosphere, is modified and attenuated by the atmospheric gases due to scattering and absorption processes. The radiant energy of the sun is spread over in all wavelengths of the electromagnetic spectrum. Since the distance between the sun and the earth is very large, the sun is considered as a point source and the radiant energy reaching the earth is, therefore, considered to be parallel. Because of the elliptical orbit of the earth's revolution around the sun and because of the tilt of axis of rotation by about 23.5° from the normal to the plane of revolution, different areas on the earth are irradiated differently, giving rise to large variations in the radiation received and leading to the occurrence of the seasons.

While the irradiance outside the atmosphere depends on the time of the year, the time of the day and latitude, the irradiance that reaches the earth's surface is strongly modified by the scattering and absorption by cloud masses of various sizes. Because of the obliquity of the axis of rotation, the angle of incidence of solar rays varies with latitude, season and the time of the day and since the length of the day varies with latitude and season, the amount of radiant energy varies from place to place and over time during a year at the same place..

The radiant energy from the sun shows a peak at around 474nm, and about 98 per cent of the energy lies in the wavelength range from 300nm to 4000nm. The energy content beyond this limit is too little to effect changes in the daily values. The extremely short wavelengths and very long wavelengths are absorbed/reflected by the upper atmosphere (in thermosphere, mesosphere and upper stratosphere) limiting the available radiant energy to UV, visible and IR wavelengths. The ultraviolet radiation, shorter than 240 nm, dissociates molecular oxygen in the mesosphere into atomic oxygen which combines with another oxygen molecule to form ozone in presence of a neutral molecule like nitrogen. The ozone thus formed absorbs ultraviolet radiation in wavelengths shorter than 290 nm and at specific wavelengths in the region 290-400nm. There are weak absorption bands by ozone in the visible spectrum also. The absorption by ozone at $9.6\mu\text{m}$ is quite strong. Radiant energy content in the wavelengths longer than $4\mu\text{m}$ is quite small and most of them are absorbed by carbon dioxide in the atmosphere and water vapour in the troposphere. Thus, the irradiance that reaches the earth's surface is restricted to wavelength range, 290 nm-4000nm. Part of this irradiance, about 31 per cent is reflected to the space by the atmosphere (the cloud-cover included) and the earth's surface. The remaining proportion reaches the surface directly and after undergoing multiple scattering by air molecules and suspended particles.

In addition to the angle of incidence, the radiant energy that is absorbed by the earth depends strongly on the absorptive properties of the surface - ice, water bodies, deserts and vegetated areas. The earth emits the radiant energy at its temperature depending on the emittance of the specific surface. Since the temperature of the surface is considerably low (about 288K on an average) compared to that of the sun, the radiance from the earth lies in the wavelengths longer than $4\mu\text{m}$ with a maximum emittance around $10\mu\text{m}$. This energy is absorbed almost totally by the succeeding layers of carbon dioxide, ozone, water vapour etc. in the atmosphere. These layers reradiate the energy in about the same wavelength range both upward and downward. Major part of the energy emitted by the earth is returned, thus maintaining the temperature of the earth and the atmosphere at an optimum level. Fig.1.1 reproduced from the Radiation Manual (1) gives the various types of interactions taking place in the atmosphere. The values shown represent the average conditions.

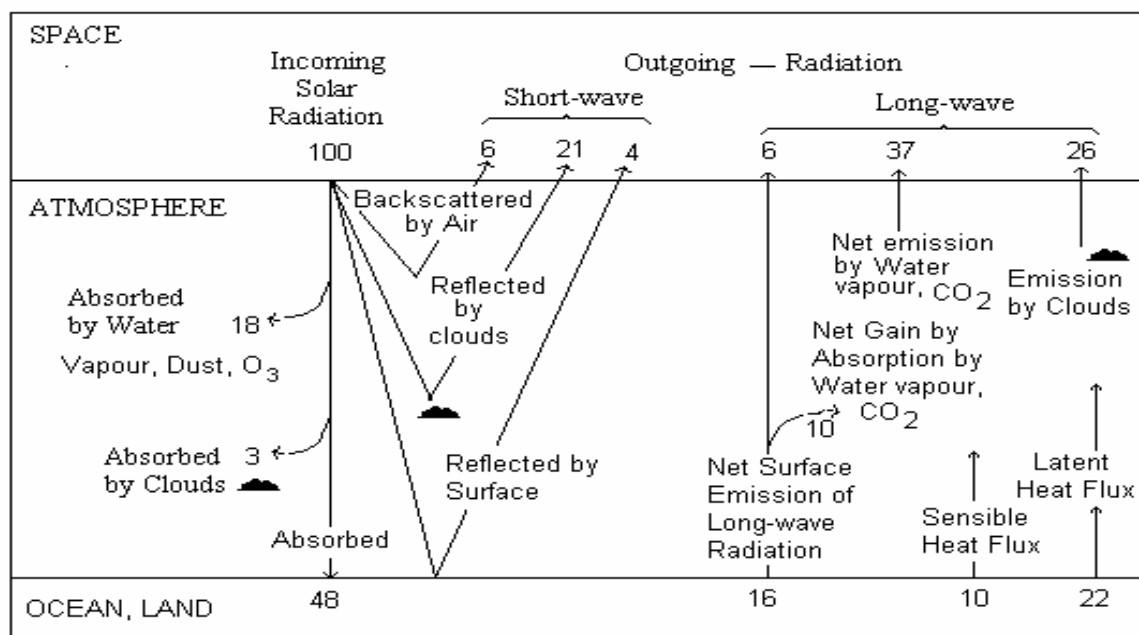

Fig 1.1: Radiation Budget of the atmosphere (Radiation Manual, WMO 1985)

The temperature field of the earth and its atmosphere has reached a near equilibrium state indicating that the average thermal radiant energy in the infra-red and the solar energy leaving the earth and the atmosphere at a given place is equal to the solar irradiance at the top of the atmosphere. The radiant energy equilibrium, however, changes at a place on a daily basis because of the changes that take place in the weather and sky condition at the place, its vegetation, emittance and topography. Thus, monitoring the different components of radiant energy at a number of places as a network activity is a necessity.

The presence of cloud seriously affects both the solar irradiance and the thermal radiant energy from the earth. Depending on the cloud thickness, water droplet content and the area it covers, the quantity of radiant energy that is transmitted to the earth's surface varies. The quantity of reflected irradiance from the cloud surface is also dependent on the type of cloud and its texture. In addition, the irradiance is seriously affected by scattering processes by the air molecules, dust and other suspended particulate matter. The scattering by air molecules, termed the Rayleigh scattering, is maximum at the lower end of the visible spectrum. The suspended particles (aerosols) made up of dust, haze, smoke particles and small water droplets cause scattering in a more complicated manner. This type of scattering is termed Mie scattering and highly variable depending on the actual prevailing conditions. Over an industrialised area, the attenuation caused by industrial exhaust is quite significant. Similar is the case with urbanised locations. The rural areas with cleaner air receive more irradiance. Water vapour is another constituent which is highly variable. Water vapour, in addition to causing scattering, becomes an absorbing agent which drastically changes the size distribution of hygroscopic particulate matter and causes near total absorption of the infra-red radiant energy from the earth. The scattered irradiance reaches the earth's surface as diffuse irradiance along with the direct beam irradiance. Since the temperature of the earth's surface is generally higher than the atmospheric layers (except in cases of inversions) the thermal radiant energy emitted by the earth's surface is greater than that emitted downward by the atmospheric layer above. Thus, there is always some loss of radiant energy in the infra-red wavelength region. The quantity of loss is highly variable depending on the concentration of the dominant constituents, viz. carbon dioxide and water vapour. Besides, the cloud cover reduces this quantity of the radiant energy very drastically.

Terminology :

Radiometry pertains to the measurement of radiant energy incident on a surface or emitted from it.

Radiant energy (Q) is the energy available due to incidence or emittance. The rate of flow of radiant energy through a surface is a power quantity (Φ) i.e. $\Phi = dQ/dt$. This is also termed radiant flux.

Radiant flux density is the radiant flux of any origin crossing unit area

$$(d\Phi/dA = d^2Q / dA \cdot dt) \text{ (Fig. 1.2)}$$

Fig 1.2: Geometry of ray-surface intersection
(US Dept of Commerce NBS Tech. Note 910-1)

Radiant exitance (M) is the radiant flux emerging from an area element ($M = d\Phi/dA$).

Radiance (L) is the radiant flux leaving a point in the source per unit solid angle of space surrounding the point.

$$L = d^2\Phi / (d\Omega \cdot dA \cdot \cos\theta) \quad (\text{Fig. 1.2})$$

Irradiance (E) is defined as the radiant flux incident on to a unit area element ($E = d\Phi/dA$).

Radiant exposure (H) is the radiant energy incident on a unit area element over time. It is the total amount of irradiance integrated over an interval of time.

Radiant intensity (I) is recommended only for the radiant flux leaving a point source per unit solid angle. The use of the term **intensity** to denote the total quantity of radiant energy, as was being done loosely, is deprecated.

Absorptance (α) is the fraction of the incident radiant flux that is absorbed by a medium or a surface.

Reflectance (ρ) is the fraction of incident radiant flux that is reflected through a surface on which the flux is incident.

Transmittance (τ) is the fraction of incident radiant flux transmitted through a medium.

Emittance (ε) is the ratio of the radiant exitance of a body to that of a black body. It is also referred to as emissivity.

A **black body** is a substance which absorbs all the radiant energy incident on it i.e. there is no reflection or transmission of the energy. The substance need not be black in colour. And in practice, a perfect black body does not exist. For a given temperature, a black body has maximum radiant exitance in all wavelengths. Substances which emit a fixed proportion of the energy of a black body and which absorb radiant energy at a fixed proportion are called **grey bodies**. They are related to the black body by emittance and absorptance of the grey body.

Meteorologically used terms (as recommended by World Meteorological Organization)

Solar radiation and terrestrial radiant energy:

The radiant energy from the sun covers the entire electromagnetic spectrum. The atmospheric interference restricts this spectrum to 290nm to 3000nm – which is called “**solar radiation**.” The maximum spectral radiant energy, irradiance, is at around 474 nm. The earth and the atmosphere being at much lower temperature (around 270K on an average) emit radiant energy in the infra-red region from 4 to 50 μ m. This is called “**terrestrial radiation**” or “**terrestrial radiant energy**”.

Direct Solar irradiance (S):

It is the irradiance of the sun emitted from the solid angle of the sun's disc, received by a unit surface held perpendicular to the solar beam. It includes a small quantity of irradiance that is scattered by the intervening medium along this axis of the cone. The attenuation, if any, is then due to the variation in the relative concentration of the individual constituents of the medium, viz. air. The solar constant is a special case, as it pertains to the value outside the earth's atmosphere and it is denoted by S_0 . The term, beam solar radiation is used to denote the direct solar beam, incident on a horizontal surface.

Diffuse Solar irradiance ($E_{d\downarrow}$):

It is the downward irradiance scattered by the atmospheric constituents and reflected and transmitted by the cloud and incident on a unit horizontal surface. This irradiance comes from the whole hemisphere of solid angle of 2π with the exception of the solid angle subtended by the sun's disc.

Global Solar irradiance ($E_{g\downarrow}$):

This is the irradiance that reaches a horizontal unit surface. It is made up of the direct solar beam irradiance and the scattered diffuse solar irradiance. Since the direction of the incident solar beam changes continually from sunrise to sunset, the cosine effect or cosine law comes into play. When a parallel beam of radiant flux of a given cross-sectional area spreads over a flat surface, the area that it covers is inversely proportional to the cosine of the angle between the beam and the normal to the surface. Therefore, the beam irradiance that heats up the area is proportional to the cosine of the angle of incidence. Thus the global irradiance at a place can be written as:

$$E_{g\downarrow} = S \cos \theta + E_{d\downarrow}$$

where θ is the angle of incidence.

Reflected Solar irradiance ($E_{r\uparrow}$):

Part of the global solar irradiance is reflected by the receiving surface (mainly the earth's surface and diffusely by the atmospheric layer between the surface and the point of measurement.) This is termed reflected solar irradiance.

Albedo of the surface:

It is the ratio of the reflected solar irradiance to the incident global solar irradiance. It is the same as the reflectance (ρ) except that its use is restricted to 'solar' wavelengths, viz. 290 to 3000nm. It is denoted by ρ . Thus $\rho = E_{r\uparrow}/E_{g\downarrow}$. The quantity of the reflected flux is the characteristic of the reflecting surface. In meteorology, albedo is also denoted by ' α '.

Net Solar irradiance (E_g^*):

It is the balance between the downward global and upward reflected irradiances. This is represented by

$$\begin{aligned}
 E_g^* &= E_{g\downarrow} - E_r\uparrow \\
 &= E_{g\downarrow} - \rho E_{g\downarrow} \\
 &= E_{g\downarrow}(1 - \rho) \\
 &= (S \cos \theta + E_{d\downarrow})(1 - \rho)
 \end{aligned}$$

The value of E_g^* is always positive.

Upward terrestrial radiant energy (E_{ℓ}^{\uparrow}):

It is the amount of radiant energy emitted by the earth's a surface upward in the terrestrial radiant energy wavelength range 4-50 μ m and reaching a surface of unit area. The energy emitted in unit time by a black body of unit area at a temperature T K is given by Stefan- Boltzman Law expressed by $E_{\ell}^{\uparrow} = \sigma T^4$ where σ is the Stefan-Boltzman constant ($5.67 \times 10^{-8} \text{ Wm}^{-2}\text{K}^{-4}$) and T is the temperature (in kelvin) (in the range of temperatures of the earth and its atmosphere). In actual cases where the emitting surface is not a black body, this relation takes the form

$$E_{\ell}^{\uparrow} = \epsilon \sigma T^4$$

where, ϵ is the emittance or emissivity of the surface.

Downward terrestrial radiant energy (E_{ℓ}^{\downarrow}):

It is the amount of radiant energy emitted by a surface downward in the terrestrial wavelength ranges. In the case of earth, it is normally the radiant energy emitted downwards by the atmosphere to the earth's surface.

Net terrestrial radiant energy (E_{ℓ}^*):

This gives the balance between the downward and upward terrestrial radiant energy expressed as the difference between them.

$$E_{\ell}^* = E_{\ell}^{\downarrow} - E_{\ell}^{\uparrow}$$

In the case of the earth and its atmosphere at lower levels close to the earth's surface, the temperature of the earth or the lower surface of the atmosphere is generally higher. Hence $E_{t\uparrow}$ is always higher than the downward radiant energy $E_{t\downarrow}$ and therefore E_t^* is generally negative, i.e. there is a loss in energy from the lower level. E_t^* becomes positive whenever inversion layers are involved where the upper layer has higher temperature.

Downward total radiant energy (Q_{\downarrow}):

This is the total amount of energy reaching a surface from above. It is made of global solar irradiance ($E_{g\downarrow}$) and the downward terrestrial radiant energy $E_{t\downarrow}$,

$$Q_{\downarrow} = E_{g\downarrow} + E_{t\downarrow}$$

Upward total radiant energy (Q_{\uparrow}):

This gives the total quantity of radiant energy reaching a surface from below. In the case of the earth, it is the energy emitted by it and the solar irradiance reflected by it.

$$Q_{\uparrow} = E_{r\uparrow} + E_{t\uparrow}$$

Net total radiant energy (Q^*) :

This is the energy balance between the downward and upward total radiant energy levels.

$$\begin{aligned} Q^* &= Q_{\downarrow} - Q_{\uparrow} \\ &= E_{g\downarrow} + E_{t\downarrow} - (E_{r\uparrow} + E_{t\uparrow}) \\ &= (E_{g\downarrow} - E_{r\uparrow}) + (E_{t\downarrow} - E_{t\uparrow}) \\ &= E_g^* + E_t^* \\ &= E_g(1-\rho) + (E_{t\downarrow} - E_{t\uparrow}) \end{aligned}$$

The net total radiant energy is generally positive during the daytime for normal surfaces of the earth due to the dominant global solar irradiance. It is generally negative during the night-time as there is no incidence of global solar irradiances. At sunrise or sunset times, the value of Q^* becomes negative due to the lower levels of global solar irradiances as compared to upward terrestrial radiant energy from the earth. Because of the strong reflectance and high albedo, Q^* may be negative for major part of the day on snow-bound areas.

Irradiation:

It is the incident irradiance on a unit area integrated over a specified time interval - generally over an hour or a day.

Air mass:

The solar irradiance passes through an atmospheric column of air which varies depending on the apparent position of the sun in the sky. The path length of the column of air is minimum when the sun is exactly overhead (at zenith position) at noon. Since the apparent path of the sun is within the latitudinal zone 23.5°N - 23.5°S, the sun will be overhead on one or two occasions only during a year at places within this zone only. On all other days the irradiance will be incident at larger angles and hence the irradiance has to pass through a longer path. At any other time of the day, the sun's rays will again have to pass through longer path lengths. This optical path length is usually called optical air mass or simply air mass. For all directions other than the vertical one, the optical air mass called relative optical air mass m_h is the ratio of the air mass along the slant path to that in the vertical. Thus, this is a normalizing factor. In a plane parallel, non-refracting atmosphere $m_h = 1/\sin h = \cos Z$ where h is the solar elevation angle and Z is the angle of incidence or the zenith angle. Taking into account the sphericity and refraction, the relation for m_h may be written as

$$m_h = 1/(\sin h + 0.15(h + 3.3885)^{-1.253})$$

where, h is the angle of elevation of the sun in degrees (1). This angle h can be worked out if the time is known from

$$\sin h = \sin \Phi \sin \delta + \cos \Phi \cos \delta \cos t$$

where, Φ is the latitude of the place, δ is the declination of the sun for the day and t is the hour angle corresponding to the actual time. The hour angle in degrees is calculated at the rate of 15° per hour and is with reference to the solar noon time when $t = 0$. As per convention, its value is taken negative in the forenoon and positive in the afternoon.

Optical depth:

The radiant energy flux which is incident at the top of the atmosphere is attenuated by the atmosphere and the aerosols suspended in it. This attenuated radiant energy is related to the incident energy by

$$S_{\lambda} = S_{o\lambda} e^{-a_{\lambda} m_h}$$

where, S_{λ} is the spectral energy after attenuation, $S_{o\lambda}$ is the spectral energy at the top of the atmosphere at the wavelength λ and a_{λ} is the extinction or attenuation coefficient for the wavelength.

This extinction is the combined effect of absorption and scattering properties of the intervening medium. This varies with the type of the absorbing and scattering material and generally depends slightly with changing pressure and temperature. The attenuation coefficients have thus two components, viz. absorption coefficient and scattering coefficient. The values of these coefficients are variable for different constituents involved in the processes and have quite a different wavelength dependence. The relationship given above is called Beer's law and also as the Bouguer-Lambert law. a_{λ} when used for the total attenuation is called the total optical depth. When pure atmosphere is considered, it is molecular optical depth. With aerosols as attenuator, it is aerosol optical depth. When only ozone is to be studied, it is referred to as ozone optical depth. The mathematical expressions are dealt separately in Chapter VI.

Atmospheric turbidity:

The direct solar irradiance on a given surface depends on the depletion it undergoes in its passage through the atmospheric column. The depletion is caused by pure air molecules and other suspended particulate matter in the atmosphere. The suspended particulate matter is a combination of substances, such as water vapour, dust, haze and smoke, or generally termed as aerosol particles. The turbidity of the atmosphere is defined as the reduced transparency of the atmosphere due to absorption and scattering of the radiant energy by solid or liquid particles, other than clouds, held suspended in the atmosphere.

There are several ways to express atmospheric turbidity. In a global network and for studying long-term changes, the techniques used should be simple and reliable. In India, Linke turbidity factor and Ångström turbidity coefficient are computed using direct solar irradiances obtained from the measurements made with pyrheliometers. Narrow band turbidity measurements in terms of spectral optical depths are worked out using narrow band pass and interference filters mounted on sunphotometers.

Unit of measurements: Radiant Energy:

The World Meteorological Organization (WMO) has adopted the use of International System of units. In conformity with this, India Meteorological Department (IMD) has been using these units for its network use. These units in use are:

Irradiance: Watt per square metre (Wm^{-2})

Radiant Exposure: Joule per square metre (Jm^{-2})

In case of spectral measurements, these units are:

Spectral irradiance: Watt per square metre per nanometre ($\text{Wm}^{-2} \text{nm}^{-1}$)

Spectral radiant exposure: Joule per square metre per nanometre ($\text{Jm}^{-2} \text{nm}^{-1}$)

As per SI recommendations, these units may be expressed in multiples of 10^3 (like kilo, mega, milli, micro and nano). In normal practice, direct solar irradiance S measured instantaneously is expressed in Wm^{-2} while the hourly values of direct solar irradiation are expressed in MJm^{-2} . Similar is the case with global, diffuse and reflected irradiances and irradiation. The terms global solar radiant exposure is recommended for global solar irradiation. Similar is the case with diffuse, direct or reflected irradiation.

The radiant exitance from a surface is normally expressed in Wm^{-2} . When it is done over an interval, the terms like radiant energy and net total radiant energy are used and expressed in Jm^{-2} , kJm^{-2} or MJm^{-2} as the need be.

The use of the units, calorie and British thermal unit are no more in use. The use of Wh or kWh is continued by technology disciplines.

The energy units used in this publication are in conformity with the SI units.

Time: The basic unit of time is second (s).

An hour has 60 seconds and a day of 24 hours has 86400 s. The time interval between two successive upper transit of a star across a meridian is known as sidereal day. In the case of the sun, the length of the day, i.e. the time interval between two successive transits of the sun across a meridian is not constant during the course of a year. The variability is due to eccentricity and obliquity. The first one arises out of the changes in the

distance between the sun and the earth due to elliptical path of the earth's orbit. This varying distance causes minor changes in its velocity. The second is caused by the oblique orientation of the axis of rotation with reference to the plane of the orbit. However, a sidereal day has a constant time duration but is not in synchronization with day-night phenomenon. It is so in the case of the solar day. To provide a uniform time scale applicable throughout the year, a fictitious mean sun is assumed. This coincides with the real sun on the vernal equinox day (March 21) of each year and the mean sun travels with a constant speed along the celestial equator. The time taken by this mean sun for two successive transits across a given meridian gives the mean solar day. Thus the time taken by the mean sun to transit across the same meridian on the next day will be slightly different with the time taken by the true sun for transiting across the same meridian on the same two days. The time of transiting across the meridian is taken as the noon time. The time at which the true sun crosses the meridian is the local apparent noon and the time reckoned with reference to this is called the local apparent time (LAT) or true solar time (TST). The other time is the local mean time (LMT) and is used for civil purposes.

The difference between LAT and LMT is known as the equation of time. This equation of time when added to the noon LMT gives the exact time in LAT which is the time when the sun will be transiting across the meridian concerned. The noon LAT gives the time when the sun will have highest angle of elevation in its apparent path across the sky. This angle of elevation will be the same at 1200 LAT at all places on the same geographical latitude across all meridians (longitudes). Also on the same latitude, the angles of elevation at equal intervals of time with reference to 1200 LAT will be the same. The time taken by the apparent sun to transit two successive meridians is 4 minutes. Thus an hour corresponds to 15° of longitude - This angle is called the hour angle of the sun (to express in a simple language). Thus the hour angle at a given time interval centred around the 1200 LAT is the same. The exact times of transit across a given meridian by the mean sun and the true sun are different on different days. For civil purposes, the concept of universal time (UT) is used. It is based on the mean solar time system derived from the earth's rotation with respect to the sun. It is based on the 0° longitude (meridian) of Greenwich. The time with reference to this meridian was called Greenwich Mean Time (GMT) and is now referred to the Coordinated Universal Time (UTC) or simply Universal Time (UT). Local mean time (LMT) is related to universal time (UT) as follows.

$$\text{LMT} = \text{UT} + \lambda$$

where, λ is the longitude of a place for which LMT is to be determined. Longitudes east of Greenwich are taken as positive and the times are added to UT at the rate of 1 hour for every 15° of longitude. It is a negative correction for longitudes west of Greenwich.

LMT, however, will be different for different locations on different longitudes. To avoid confusions due to use of different LMTs within a contiguous areas, say a country, the concept of standard times (ST) is introduced. The World is divided into standard time zones for every 15° of longitude starting from 0° longitude of Greenwich. For India the standard longitude is taken as 82.5°E and hence the Indian Standard Time (IST) is 5 hours 30 minutes ahead of UT.

To deduce LAT for given place in India, the following is to be worked out

$$\text{LMT} = \text{IST} \pm 4 \times (82.5 \pm \text{longitude of place})$$

$$\text{LAT} = \text{LMT} \pm \text{Equation of time}$$

The equation of time used is incorporated in the Ephemeris. This can also be worked out using empirical relation given in Chapter VI.

Applications of Solar Energy:

Solar energy in its original form provides heat and light for the life to be sustained on the earth. During the earliest periods man started using wood, water and wind for his energy purposes. During the recent past, coal and subsequently petrol took over and they became the primary providers of energy for most of the activities. Coal gas has become another source of energy provider. Coal, Petroleum and gas are all products of solar energy over the ages. Energy derived from these sources has tremendously helped the accelerated pace of development but at a cost, causing serious degradation in the environment. The waste including emission, contributes to the environmental pollution. The sources of these energy, whether they are thermal, hydroelectric or atomic, are in centralised locations and the energy has to be transported to different areas with attended losses due to leakages and theft involved in their transmission. Also the resources including the “atomic” raw material are limited. Petroleum has been tapped quite aggressively and in the near future, its output will start dwindling. Coal and gas may hold for a little longer time. Thus a necessity arises for exploiting the natural and unlimited resources like the energy from the sun, wind and biomass and oceans. The ever burgeoning demand for energy for utilisation has thus necessitated the need for augmenting the resources.

Energy from the Oceans:

The kinetic energy stored in the waves and the temperature difference produced by the solar heating of the top skin of the ocean water surface allow the oceans to be vast storehouse of energy. The oceans may offer poor thermodynamic efficiency due to the small differences in temperatures among the layers. However, the available amount of thermal energy is phenomenal due to the vast areas of ocean surfaces. The cost of using the temperature gradients for practical utilization is, however, quite high especially when we take the corrosive marine conditions into account. The ocean waves may also be used to operate turbines which will generate power.

Energy from Wind:

Windmills are used to power irrigation pumps and to drive small electric generators which can charge batteries. A wind mill or a wind turbine converts kinetic energy of the air in motion into mechanical motion usually by using a rotating shaft. The energy due to the wind is proportional to the cube of wind velocity. Wind power installations have become quite common. The cost estimates for installing electric power generation units in regions where wind speeds are high are seen comparable to those of fossil fuel energy sources. However, the installations have to be fairly large to obtain reasonably large amounts of power and have to be placed at regular distances. It is also a fact that winds are never steady and highly variable with the prevailing weather. Because of this, the energy has necessarily to be stored.

Biologically converted Energy:

Photosynthesis is a natural process in which plants convert solar energy and store it. This provides a vital part, though small, of our energy consumption in the form of food. The wood also has been the sole source of heat over thousands of years. It is also the process that in the course of millions of years, produced our fossil fuels which are currently in use. All plant residues can always be fermented to produce biogas. Industries based on solar-dependent raw materials like vegetations would be able to draw its energy from biological sources. Thus more efficient use of biomass inputs becomes a practical feasibility. Chemical products from fossil hydrocarbons pose the major problem in waste disposals. Breaking synthetic compounds into component molecules is complicated and costly and hence recycling is very difficult. Since they do not degrade naturally, their disposal can only be done by burning or burial, causing woeful environmental problems. Such problems do not happen with the degradation of plant resources. The biomass (plants, crops and trees)

can easily be converted into fuels and bio-products. Anaerobic digestion of wet biomass results in the generation of methane. At high temperatures, dry biomass enables formation of inflammable gas mixtures of hydrogen, carbon monoxide and methane. Liquid fuels like ethanol can be obtained by fermentation of sugar. Thermochemical conversion processes give pyrolysis oils or methanol from biomass. We may get biodiesel by processing vegetable oils. The resulting liquid and gaseous fuels can be effectively used to produce heat and power. Waste materials of biological origin can thus be used as feedstock for energy conversion.

Energy from Solar Radiation:

Energy from solar radiation can be derived by thermal conversion wherein the heat generated due to irradiation is used to operate a system and by direct conversion into electrical energy by solar photovoltaic methods.

Solar Thermal Energy:

A solar energy collector has a sun-facing surface and when irradiated by the solar irradiance gets heated up. The heat is then transferred partly to a working fluid in contact with the absorber. To reduce the heat losses to the surrounding and to make it work at optimum efficiency, a glass sheet covers the absorbing surface. However, losses due to convection and radiation cannot be eliminated totally. Evacuation of the area near the hot absorber and selective coatings if used judiciously, decrease the losses. The simple thermal conversion devices operate over a temperature range up to about 365K. These devices are mainly used for providing hot water, drying of food and agricultural products, solar desalination, space heating and to operate absorption-type air-conditioning systems. Where higher temperatures are needed, concentrating systems are used. Operating temperatures could range from about 400K for industrial process heat systems and steam cooking systems to about 700-800K for electrical power generation plants and to few thousand kelvin for high technological applications including hydrogen generation.

Photovoltaic Conversion:

Photovoltaic cells directly convert sunlight into electricity without going through any intermediate stage. They are normally rugged, simple in design and need little maintenance. The photovoltaic based devices can be used as stand-alone to get an output ranging from microwatts to megawatts. The power derived from such devices has wide use reducing the dependence on the conventional electric supply.

Solar Photochemical Applications:

It is well known that the colour of materials fades, few other materials deteriorate and the skin gets sunburn due to long exposure to sunlight. It is, therefore, natural to deduce that sunlight could be of use to break up toxic chemicals. Early days have seen that the human dwellings were designed to maximise sunshine in the interiors, obviously to act as disinfectant and to check the growth of micro organisms.

Photolysis is the process in which the sunlight is used to trigger chemical reactions by direct heating. If a catalyst is employed, the process is known as photocatalysis. Photocatalytic reactions can be effectively used for detoxification, disinfections and production of hydrogen. And hydrogen energy systems, especially as fuel cells, may, in the near future, become a clean solution to transportation needs. Hydrogen is also likely to become a good solar energy storage that can be transported over long distances.

Hazardous pollutants in the environment can be destroyed by solar photo-catalytic oxidation or reduction processes. The treatment of ground water, industrial waste water and contaminated air and soil can be detoxified by solar irradiation. Titanium dioxide is insoluble in acidic solutions under most conditions. They are stable under irradiation and non-toxic. The near UV radiation at 388 nm activates the titanium dioxide and makes it useful to serve as a photocatalyst. Solar photo-catalytic reactors have concentrating and non-concentrating designs. The fluid that is to be treated must be transparent to UV radiation. Non-concentrating reactors, unlike the concentrating type, can use the diffuse part of solar UV radiant energy as well. The non-concentrating reactors have designs of flat plate, tubular or shallow solar pond.

UV irradiation can also be used for disinfection of biological contaminants. Several common bacteria are destroyed in few minutes on solar exposure in the presence of titanium dioxide. Without the catalyst, it may take an hour or more to effect the disinfections. In addition, the use of titanium dioxide effectively causes deodorisation of air. It is becoming feasible for the photocatalytic process to become a viable technique to control indoor air quality also.

Need for Solar Radiation Data:

A whole array of applications, viz. thermal conversion, photovoltaic conversion, photochemical utilisation, biomass conversion, passive solar lighting and heating of buildings, detoxification etc. is becoming apparently viable and enhances the society's

energy management planning and hence its efficient applications. The economics of these technologies depend on the efficiency of the utilising processes, so that the operating costs are comparable, if not cheaper, with the present day processes based on conventional fossilized energy utilisation. Thus, to design operating systems which will have the highest achievable efficiency under comparable costs, the reliable database on different aspects of solar radiant energy is essential. The more accurately the solar resources are known, the better becomes the system design. The radiant energy available at a location changes throughout the day and year due to varying weather patterns. By knowing the variability, storage systems can be designed and used optimally. Solar radiation data also help determine the best geographic location for maximum utilisation as it will have a direct influence on the design of the systems. Photovoltaic and photochemical conversions need spectral distribution over space and time. Location, climate and atmospheric conditions have strong influences on the spectral distribution of solar irradiance. This handbook thus strives to present the available radiation data in the total spectrum and in the different spectral bands as measured in about 23 stations in India, along with supporting data on general weather at each of the stations.

MEASUREMENT OF RADIATION PARAMETERS

CHAPTER II

MEASUREMENT OF RADIATION PARAMETERS

Introduction:

Radiometry is the science of radiation measurement. It is concerned with the detection and measurement of radiant energy either in separate wavelengths or integrated over a narrow or broad wavelength band. It also concerns with the interaction of radiant energy with matter in such ways as absorption, reflectance, transmission and emission. Meteorological science normally measures the radiation over specific wavelength bands and over a known length of time.

Radiometer is a device to measure the quantity of radiant energy. It is designed to convert the energy of incident radiation into another form, for the determination of the quantity of the radiation that is incident on the device. The device may provide an electrical output which will be a useful measure of the incident radiant energy in quantitative terms.

Radiation detectors convert radiation into energy of other types, such as electrical, thermal, chemical, optic-acoustic and pyroelectric. Even the phenomenon of heating affects the materials, thereby, causing changes in mechanical, electrical, photoelectrical and photochemical properties. The degree of change in the measurable output, however, depends on a variety of variables and the quantity of incident radiant energy. A part of this incident energy always goes to change the internal energy of the detector and hence it is not available for measurement. In addition, there are other intrinsic losses due to reflection, exchanges with its environment etc. Thus, the quantity as measured by a detector is always

lower than the actual incident quantity of radiant energy. Some of these losses may be accounted for by careful laboratory measurements and quantified, leading to a measurement which will be as close as possible to the true value. Such an experimental determination is called characterisation.

Meteorological practices generally use thermal detectors and photoelectric detectors for measuring the radiant energy. Thermal detectors are used for non-selective measurements over wide spectral ranges. Photoelectric devices are used for measuring radiant energy in narrow spectral bands. However, the measured value cannot be said to be accurate due to uncertainties caused by various inherent sources of errors. The deviations from the true value give rise to uncertainty in the measured values. Besides, the intrinsic uncertainties due to changes in internal energy, the accuracy of measured value depends on several factors, some of which are listed below:

- (a) Resolution: the smallest change in the radiant energy which can be detected by the instrument.
- (b) Stability of sensitivity over time
- (c) Linearity of output with irradiance changes.
- (d) Spectral response over a wide range
- (e) Directional response due to changes in azimuthal direction, zenith distance and tilt of the sensor surface.
- (f) Response time of the sensor or measuring system.
- (g) Changes in sensitivity due to changes in the environment, especially the dependence on temperature changes.
- (h) Absence of zero-point depression due to sudden changes in irradiance levels. This shift in zero-point may occur when the colder reference becomes warmer than the irradiated area due to sudden changes in irradiance and as the colder reference is not subjected to direct irradiation in most cases.
- (i) Uncertainties with the auxiliary equipment.

Classification of radiation instruments

Most of the radiation instruments, generally used on network scale for meteorological purposes, have thermal detectors. They are exposed outside throughout the year under all environmental conditions and at different locations with varying climatological conditions. Most of them have wide spectral ranges, viz. 300 - 3000nm and 4 - 50 μ m. Photosensors are used mainly for measurements of optical depths. Accordingly, the World Meteorological Organisation (WMO) has classified the radiation instruments into different groups.

- (i) **Pyrheliometers:** These measure direct solar irradiances. The solar radiation is incident perpendicularly on the receiving surface. The normal incidence can be achieved by mounting it on an electrically or mechanically driven solar tracker or manually, in case of instantaneous measurements and using a sighting device. The field of view is 5° or slightly more. By using broad-band filters, spectral measurements of irradiance can also be made.
- (ii) **Pyranometers:** These measure solar irradiation received from a solid angle of 2π steradians on a horizontal surface. They give global solar irradiance. When a shading device keeps the sensor under shade, the instrument measures diffuse solar irradiance. In an inverted position, it measures the solar irradiance reflected by the underlying surface. The instrument can also be used on sloping surfaces and facing different directions to obtain the solar irradiance from different orientations.
- (iii) **Pyrradiometers:** The total energy contained in both solar and terrestrial radiant energy wavelengths is measured by pyrradiometers, either in the upward or downward directions. In this case, the temperature of the measuring sensor surface has also to be independently measured or a compensation electrical circuit has to be developed, to account for the loss in thermal energy from the sensing surface and obtain the true value of the radiant energy.
- (iv) **Pyrgeometers:** These measure the net terrestrial radiation only. They are solar blind. These are provided with suitable filters to prevent the strong solar irradiance during the daytime.
- (v) **Net pyrradiometers:** The balance between total downward and total upward radiant energy or the net radiant energy, is measured by net pyrradiometers. The radiant field is 4π steradians.
- (vi) **Sunphotometers:** These are used to measure the irradiance in narrow spectral bands using narrow band pass or interference filters. These measurements are used to derive the optical depth of the atmosphere. Photo sensing detectors are used for the purpose.

Instruments have to be selected appropriately depending on the end uses of the data obtained. Certain instruments are designed to perform better for certain climatic conditions, irradiance levels and orientations.

Details of Radiation Instruments

Different types of instruments in use in a network are discussed in the following sections:

(I) Pyrheliometers:

Pyrheliometers by definition measure direct solar irradiance which is received by a surface held perpendicular to the incident radiant energy. The thermal sensor used is normally a plane surface painted black or a cavity which absorbs the incident irradiation. The view limiting system using a series of diaphragms, ensures that the sensor receives only the radiant energy from the sun and a narrow annulus of the sky which is unavoidable. ISO and WMO recommend that the opening angle be 5° and the slope angle be 1° . Since the sensor has to be perpendicular to the incident irradiation continually during a measurement, the construction of the mounting must allow for the rapid and smooth adjustments of azimuth and elevation positions. This adjusting mechanism can be a manual operation or an automatic sun-following system. A sighting device ensures the proper orientation of the sensor to be always perpendicular to the incident radiant energy. To ensure high accuracy in measurements, proper adjustments, regular maintenance and use of sufficiently accurate auxiliary equipment have to be strictly put into practice.

There are two categories of pyrheliometers, absolute self calibrating radiometers and instruments used for field use. Self calibrating radiometers do not depend on another standard equipment and in this sense, they are termed absolute radiometers.

(II) Cavity Radiometers:

Absolute radiometers are capable of providing data of the highest accuracy. They mostly employ a cavity receiver as the receptor of the solar irradiation and a heat flux transducer to monitor the power. The absolute radiometer can define the irradiance without reference to other standard sources and radiators. The electrical calibration is carried out by using electrical power in place of radiative power. Normally, two opposing inverted cavities (now-a-days conical shaped ones rather than spherical) are used, one to receive the solar irradiation and the other to compensate the heat gained (kept at the rear of the exposed

cavity). The heat flux transducer can be a thermopile or a platinum resistance thermometer. The cavities are generally wound with an electrical heater and both are securely in thermal contact with a massive heat sink base. Most of the available radiometers use the passive mode of operation in which the receiver is alternately exposed to solar irradiation and then electrically calibrated heat flow transducer. The receiver is not electrically heated during the period when the cavity gets irradiated by the sun's rays. Irradiance is derived as the power per unit area. In the active mode, a constant temperature difference along the heat flow resistor during both exposed and reference phase of a sequence, is controlled by a control system which automatically adjusts the power to the heater. Some radiometers can be used in a differential mode, in which while the front cavity gets heated by irradiation, the heat generated is measured by electrically heating the compensating cavity so as to achieve an equilibrium condition between the two modes. This type of operation is said to be in Ångström mode.

Thus, by its very principle of construction and operation, the cavity radiometer can become an ultimate accurate measuring instrument and be termed as a primary standard. However, the cavity radiometer has certain departures from the ideal behaviour. Most of these can be quantitatively measured. Some of them are:

- (i) Non-equivalence in heating by solar irradiation and electrical current
- (ii) Diffraction at the view limiting apertures
- (iii) Imperfect thermal coupling between the cavity and the heat sink
- (iv) Cavity losses which include the radiant energy reflected at the aperture, radiant energy lost through the aperture due to emission from the cavity and the temperature gradient within the cavity
- (v) Heat losses through the power and sensor leads
- (vi) Errors in the electrical power measurements.

However, most of these uncertainties can be quantitatively determined and incorporated in the calibration factor of each instrument.

Different types of cavity radiometers widely used are shown in **Fig.2.1**. Besides cavity radiometers, two other instruments also qualify for the class "Reference Standard Pyrheliometer". These are the silver disk pyrheliometer and the Ångström compensation pyrheliometer.

(III) Silver disk pyrhelimeter:

The pyrhelimeter developed by Smithsonian Institution, Washington, USA, has a blackened silver disc floating in a small mercury reservoir but separated from its direct contact by the use of an extremely thin steel disc. The opening angle is 5° , achieved by a series of blackened diaphragms mounted at regular intervals in a long tube. The heat gained by the silver disc on irradiation, is measured by a mercury thermometer mounted with its bulb in the mercury reservoir and the stem bent at right angle and mounted by the side of the pyrhelimeter tube. The measurements involve elaborate procedures for noting the temperature at specified timings (in seconds). If this is properly carried out, the instrument is capable of providing data of very high accuracy, better than 0.5 per cent of the true value. However, even a slight error in the timings, can give rise to very significant errors in the data. This instrument is not used these days.

(IV) Ångström compensation pyrhelimeter:

This is more widely used at the reference standard level. It has basically two thin blackened manganin strips below which two copper-constantan thermocouples are attached. The thermocouples are in good thermal contact with the strips, but electrically insulated. The measurement involves in exposing one strip to the solar irradiation while the other is shaded, setting up a temperature difference at the thermocouple junctions.

When the thermocouples are connected to a sensitive galvanometer, the thermoelectric e.m.f. generated due to the temperature difference causes a deflection in the galvanometer. An electrical current is then passed through the shaded strip to heat it, thus raising the temperature at the thermocouple junction below the shaded strip. This causes the deflection in galvanometer to return to the original zero level when the rate of solar heating is exactly compensated by the electrical heating. The square of the compensating current is proportional to the solar irradiation that caused the heating of the exposed strip. To ensure that the sensing strips are always perpendicular to the incident irradiance, a sighting device is used along with a pinion and screw arrangement. Three circular diaphragms with rectangular aperture opening, help in ensuring that only the desired direct solar irradiance is incident on the strips.

By using broad band filters, the instrument measures the spectral distribution of the incident direct solar irradiance. From these spectral data, it is possible to derive the atmospheric transparency and the atmospheric turbidity parameters.

Ångström pyrheliometer, though capable of high accuracy - better than 0.5%, is useful for instantaneous measurements only and cannot be used for the continuous recording of direct solar irradiation in the field. For this purpose, pyrheliometers using thermopiles as sensors and having an opening angle of 5° and a slope angle of 1° are used. They are mounted on a solar tracker, so that the sensor is always perpendicular to the irradiance from sunrise to sunset. The millivolt output is recorded on a potentiometric recorder or by a data logger. It is essential that the mounting of the tracker is properly done for N-S alignment, for exact horizontality of the base and for the latitudinal inclination of the place. The frequency of the power supply has to be very stable and maintained within narrow limits, so that the tracker can faithfully follow the apparent movement of the sun.

PACRAD

HF

PMO-6

TMI

Fig 2.1: Cavity Radiometers with read-out units

The solar tracker is normally driven by an accurate synchronous motor. Active solar tracking by using photo detectors and also by computer based drive system are increasingly being brought into use. Since continuous recording is involved and the opening angle is kept at 5° to eliminate recording of the strong scattered irradiation from the sky immediately around the sun's position, it is necessary to have periodic checks on the correct orientation of the pyr heliometer to the sun. If not done, the sun's disc may be obstructed by the view-limiting diaphragms and apertures, resulting in the erroneous recordings.

To obtain measurement of full solar spectral range, it is ideal not to use any window material in the case of pyr heliometer used for continuous recording. This may, however, lead to damages to the sensing element due to water, dust and other depositions. Therefore, most of the field instruments use a window to the entrance aperture, made either of quartz or of glass. This leads to a narrower spectral range of irradiance due to limits of spectral transmission of these window materials.

In most of the networks where continuous recording of direct solar irradiance is made, pyr heliometers made by Eppley Laboratory, Kipp and Zonen or EKO are used. A brief description of these instruments is given below:

(V) Eppley normal incidence pyr heliometer (NIP):

The sensor is an electroplated copper-constantan wire wound thermopile which is covered with a blackened silver foil. It is mounted at the base of a double-walled tube. The opening angle is $5^\circ 43' 30''$ obtained with an aperture-length of the tube ratio as 1:10. This field of view is achieved by proper positioning of field limiting diaphragms inside the blackened tube. The tube is filled with dry air and sealed using a 1mm thick infrasil glass window. Two flanges, one at each end of the tube, are provided with a sighting arrangement for ensuring the normal incidence of the solar irradiation. A filter wheel with suitable band pass filters can also be used for spectral measurements. The instrument has a linearity of $\pm 0.5\%$ and response time of 1 second and the output is temperature compensated. The instrument has an excellent reputation of reliability and stability of calibration over years and ease of operation. These salient features have resulted in designating it, by many institutions, as a working standard for calibrating other radiation instruments.

(VI) Kipp and Zonen pyr heliometer has a hood to act as a rain screen to prevent deposition of water on the quartz window at the entrance aperture. This has an opening angle of 5° and a slope angle of 1° . The response time is 7 seconds for 95% of change. This

instrument also has provision for a filter wheel to be mounted for spectral measurements. The non-linearity in the output is within 0.2%.

(VII) Actinometer A80 is developed by Main Geophysical Observatory, St. Petersburg. The sensor is a thermopile, star type in shape, of manganin and constantan bands. The cold junctions of the thermopile are fixed on a copper ring with good electric insulation. A blackened thin silver foil is pasted at the top of the hot junctions. The response time for this type of instrument is 4s for a 1/e response. It has an opening angle of 10° and slope angle of 2.3° .

(VIII) EKO precision pyrheliometer uses a 25 junction copper-constantan thermopile which is mounted at the base of the housing tube, which is double-walled to minimize the environmental effects. A series of diaphragms limits the opening angle to 8° and the slope angle to 1.5° . The response time for 1/e of the signal is 1.4 seconds.

Some of the pyrheliometers are shown in **Fig. 2.2**.

Mounting of the field pyrheliometers:

Since the pyrheliometer is to continuously record the direct solar irradiances, the instrument has to faithfully track the sun, so that the incident beam is always normal to the sensing surface. The small opening angle ensures that the aureole radiation is minimum. This would then necessitate that the tracking has to be accurate, lest a part of the sensor gets obstructed by the diaphragms, leading to erroneous recorded data.

Normally, the solar trackers are driven electrically by synchronous motor working on a power supply of stable frequency. Computer controlled driving systems or solar sensing devices using photo-sensors are also in vogue.

All solar trackers use equatorial mounting in which the axis of rotation of the tracker is parallel to the rotational axis of the earth. A solar tracker has a heavy horizontal base, hour-angle axis, azimuthal rotation axis and axis of the mount. The hour-angle axis is the axis of rotation of the mount. The orientation around the vertical is the azimuthal rotation axis and the axis of the mount is the declination of the axis with movement at right angle to the hour angle axis and on which the pyrheliometer is mounted.

To ensure proper tracking, the base has to be exactly horizontal. The hour angle axis should be at an inclination corresponding to latitude angle at the site. This hour angle

axis arm is to be exactly oriented in the North-South direction. This is best done at solar noon when the shadow of all sharp edged objects lie in the exact N-S direction and can easily be marked. The hour angle arm can then be adjusted parallel to this marking. If levelling and 'latitude' inclination are correctly done, the N-S alignment will normally be perfect. The WMO Radiation Manual (1986) gives the instructions on the installation of the tracker.

The automatic solar tracker is a 2-axis azimuth and elevation device programmed to align the instruments to the sun. The solar tracking is done using a micro-computer based program which calculates the position of the sun at the specific time and transmits pulses to the drive which then operates two stepper motors. The motors position the tracker and hence, the instruments properly. In the Eppley model the signal cables and the motor drive cable are routed through the rotation axis and out to a stationary connector to eliminate any chance of coiling due to continuous 360° rotation over few days. It is possible to achieve a tracking accuracy of 0.1° with 2-axis solar trackers. After initial set-up, the tracker will follow the sun without any need for adjustments, except for the periodic resetting of the system clock. However, a periodical physical verification on the solar tracking is required.

Scale of radiation measurements:

Prior to 1956, the radiation measurements were being made with reference to the two standards-Ångström pyrheliometer at Stockholm, Sweden and the silver disk pyrheliometer kept at the Smithsonian Institution, Washington. The calibration factor of the standard Ångström pyrheliometer was derived based on the basic dimensions of the sensor, its resistance and absorptivity. This was standardized in 1905 and the base reference to this was being called the Ångström Scale 1905. The Smithsonian Institution derived the calibration factor of its pyrheliometer by calorimetric methods with reference to its standard water flow pyrheliometer. Measurements based on these pyrheliometers were referred to a standard called Smithsonian Scale 1913. There have been frequent inter-comparisons of the two scales through their secondary standards. Careful analysis of data established a mean difference of 3.5 per cent between the two scales.

In 1956, the International Association of Meteorology and Atmospheric Physics (IAMAP) in its meeting at Davos, Switzerland considered these data and formulated a new scale for normalizing the two scales and the data obtained based on them. It was called International Pyrheliometric Scale 1956 (IPS 1956). To reduce the calibration factors of different sensors and the data obtained earlier to this newq IPS 1956 Scale,

- (i) results based on Ångström scale 1905 are to be increased by 1.5 per cent and
- (ii) results based on Smithsonian scale 1918 are to be decreased by 2.0 per cent

The earlier data were adjusted to this IPS 1956 scale. However, careful measurements, carried out later, showed serious differences among the standard Ångström pyrheliometer maintained then at the World Radiation Centre (WRC) Davos, Switzerland. In the meantime, highly accurate and self-calibrating cavity radiometers have been designed and were being used. IPS 1956 scale showed substantial difference of 2.2 per cent with respect to the cavity radiometers.

A large number of comparative calibration data led to the definition of a new scale World Radiometric Reference (WRR). The cavity radiometers work on the principle of substitution of thermal heating by electrical heating which can be very accurately determined from fundamental SI units and do not require another standard for its calibration. It is related to IPS 1956 by:

$$\frac{\text{WRR}}{\text{IPS 1956}} = 1.022$$

The use of WRR has now been made mandatory since January 1981. Its absolute certainty is estimated to be within 0.3 per cent. Thus, all the instruments now in use and the data derived therefrom are with reference to WRR. The WRR is maintained and checked regularly by WRC at Davos, using a World Standard Group of Radiometers of different makes. The data presented in this book are in SI units and with reference to WRR.

Sunphotometers:

All instruments which are capable of measuring the spectral irradiance can be broadly termed as sunphotometers. However, broad-band spectral measurements yield attenuating factors which are normally termed as atmospheric turbidity. When narrow band spectral measurements are made using interference filters or monochromators, the attenuating factors derived from the data are called aerosol optical depth.

A sunphotometer consists of a narrow band interference filter and a photovoltaic detector, usually a silicon photodiode. Full field of view is normally 2.5° with a slope angle of 1°. Since both the interference filter and the photodiode can exhibit changes, frequent calibration is a compulsory requirement.

The basis on which sunphotometers were made, is to quickly evaluate the atmospheric particulate load condition, rather than to exactly determine their concentration. To meet this, F. Volz designed a simple instrument - the sunphotometer - using selenium cell to receive irradiance through a fairly narrow band pass filter. The photoelectric current developed by the selenium cell when exposed to the solar irradiation, is measured on a microammeter. Knowing the extraterrestrial value, it is possible to work out the turbidity factor.

Ångström Pyrheliometer

Silver Disk Pyrheliometer

Normal Incidence Pyrheliometer

Linke-Feussner Pyrheliometer

Fig. 2.2: Pyrheliometers

WMO has recommended the use of wavelengths, viz. 368, 500 and 778 nm for the determination of aerosol optical depth by the use of interference filters with a bandwidth of ± 5 nm and with the central wavelengths of the filters being within 2nm of the specified range.

A number of makes of sunphotometers are available for the measurement of optical depths. EKO Trading, Tokyo, Japan; Noll GmbH, Germany and Kipp and Zonen, Holland are some of the makers of new types of sunphotometers. They use interference filters, 4 to 7 in number, in different wavelengths. Measurement at the wavelength of 500nm is mandatory. Kipp and Zonen has also made a grating sunphotometer with half-power bandwidth of 3.6 nm, so that measurements from 350 to 1050 nm are feasible. The user can choose the wavelengths according to his requirement. In all the models using filters, the detector is generally a silicon photodiode which gives output as the different filters mounted on a rotating wheel are brought in the field of view in succession. Hand-held models and models that can be mounted on solar trackers for frequent monitoring are available with suitable software for calculating the aerosol optical depth and size distribution of the particulate matter in the atmosphere.

The Microtops-II sunphotometer made by Solar Light Co, USA uses five interference filters with central wavelengths at 368, 500, 675, 778 and 1020nm with half width of 2.4nm. The instrument is equipped with five independent and accurately aligned collimators at the end of which five GaP photodiodes are located. The instrument has got sighting arrangement. When the instrument is directed to the sun, all the five photodiodes with their aligned optical arrangements, receive the solar irradiation in the appropriate spectral current ranges of the individual filters. The output is proportional to the radiant power incident on the photodiodes. These signals are amplified and then converted to digital form by high resolution A/D converters. The signal processing is done serially. The instrument is also equipped with a temperature sensor and a pressure sensor to provide the data on air temperature and atmospheric pressure. The manufacturer claims that the amplifier's offset is automatically compensated every time the instrument is switched on and that the offset and full scale of A/D converters are automatically checked and adjusted for every scan. The full scale calibration is achieved by the use of a high performance voltage reference. Real time and date needed for calculating the zenith angle is provided by an onboard clockwork. The measurement can be done by holding the instrument by hand or by mounting it on a stand with azimuthal and vertical adjustments facility. The instrument is provided with necessary software algorithms which compute immediately the atmospheric optical depths at different wavelengths for display. Real time spectral irradiances in Wm^{-2} for each filter and the photodiode output in mV are also displayed. The correction for the changes in sun-earth

distance and the optical air mass is also computed internally and the values are available on the display.

Pyranometers:

The most widely measured component of solar radiation is the global solar irradiance. This irradiance is made of the diffuse solar irradiance and the direct beam irradiance. Thus it is necessary that the instrument, pyranometer, should have a field of view of 2π steradians. The pyranometer may be used to record irradiances on different inclined surfaces and for different orientations. When used in inverted positions, the solar irradiance reflected by the underlying surface is measured. When the pyranometer sensor is shaded from the direct beam irradiation, it measures the diffuse solar irradiance from the sky.

A pyranometer is used to measure the solar irradiation within the spectral range 290-4000 nm and hence it is invariably provided with hemispherical glass windows. In case of the sensors which are completely black, two hemispherical glass domes are used to prevent disturbances to the radiant energy equilibrium conditions due to wind and other transitory environmental changes which may cause changes in the infra-red radiation field of the dome. The sensors of pyranometers used for climatological purposes are normally made of thermopiles. Other types of sensors use photosensors, pyroelectric or bimetallic sensors. As pyranometers are installed in open spaces and left to record continually under all weather and environmental conditions, they must be robust and stable in their performance. As the cold junctions are to be maintained at the ambient temperature, provision for circulation of air is incorporated which makes it necessary that suitable desiccating system is included in the design itself. Pyranometer used for continuous recording of data are normally provided with a guard plate, so that direct sun rays do not irradiate the body of the pyranometer at any time of the day.

Use of the pyranometer exposed in the field introduces unavoidable errors, most importantly due to variations in the direction of incident irradiation during the day and due to changes in the atmospheric temperature. The directional response of a pyranometer is affected by deviations from the cosine law, changes in incident irradiation due to changes in solar elevation and solar azimuthal positions, and due to the sensor surface not being exactly horizontal. The performance of the instrument is also dependent on sensitivity, stability of calibration, response time, cosine response, azimuth response, tilt response, linearity of output, temperature dependence and non-uniform spectral response in the entire wavelength range. The performance of the pyranometer is also subject to thermal shocks

due to passing clouds and depression of zero under such circumstances. All these factors affect the pyranometer sensor causing changes in the calibration factor over a period of time, and therefore, it has to be checked regularly. To reduce the effect of temperature dependence, some of the manufacturers provide ventilation attachments which circulate air over the entire instrument. This also helps in removing moisture formation on the glass. In places where snow occurs, warm air circulation is also normally carried out to keep the glass hemisphere free of solid or liquid water depositions. Depending on the performance characteristics, the pyranometers are classified and put into use for specific purposes based on the accuracy requirements of the data needed.

Following are some of the widely used pyranometers:

(i) Eppley precision spectral pyranometer (PSP):

One of the most widely used instruments over long periods, PSP has a wire wound copper plated constantan thermocouple as the sensor. A silver foil in good thermal contact, but electrically well insulated from the thermopile, covers the circular thermopile and is coated with optical black. Two concentric glass hemispheres (WG-T), 50mm and 30mm in diameter, protect the instrument from the environment and also enable the transmission of solar irradiation in the required spectral range. A white painted guard plate protects the body from direct heating. A silica gel container is also attached to keep the interior dry. The outer 50mm hemisphere can be replaced, if needed, by coloured glass hemispheres for making spectral measurements.

PSP pyranometer has provision for temperature compensation by using a thermistor in contact with the thermopile. Its performance characteristics alongwith those of others are given in Table 2.1.

(ii) Eppley Black and White pyranometer:

The sensor is again wire wound copper plated-constantan thermopile and has built-in temperature compensation. The top silver foil is painted alternately black with optical black and white with barium sulphate. It uses a single 50mm hemispherical glass dome. While PSP has the precision required for a secondary standard, the black white pyranometer is recommended for network use only.

TABLE 2.1
Performance features of pyranometers of different makes

	CM -5	CM – 11	B & W	PSP	STAR	M-60 M	IMD
Sensitivity ($\mu\text{V W m}^{-2}$)	10 -12	4 – 6	10 -12	9	2 – 4	11	4 – 6
Impedance (ohms)	8 – 12	1000 – 1500	300	650	5	25 – 30	13 – 18

Stability	Stable	+ 0.5% per year	Stable	Stable	Stable after first 6 months	Stable	Stable after first 3–4 months

(iii) Kipp and Zonen CM-10/CM-11/CM-21 pyranometers:

These use constantan-manganin thermopile with its 100 junctions imprinted on an alumina ceramic substrate in a circular pattern using thin film technique. The edges which are in good contact with the body, serve as cold junctions and the central parts as hot junctions. Because of the circular pattern of the sensor, the errors due to directional changes are kept minimum. Temperature compensation is provided by a second sensor mounted below the first one. It has two hemispherical glass domes, 30 and 50 mm in

diameter. A compensation circuit incorporated in the second sensor prevents temperature-induced drifts in the zero. According to the manufacturer, these instruments do not have any cosine error up to zenith angle of 80° and the output does not vary when the instrument is used in a tilted position.

(iv) Schenk star pyranometer:

This pyranometer consists of 16 copper plates arranged to radiate out from the centre. These are mounted on insulating base made up of concentric cork rings forming segments which are painted alternately with optical black and white (reflecting) paints. Below the copper plates, copper-constantan or manganin-constantan thermo junctions are soldered, to form a 32 junction thermopile. In some models, the segments used are 12 and the number of thermo junctions is 72. The junctions under black plates form the hot junctions and those under white ones form the cold functions. The instrument has a 70 mm hemispherical glass dome since both black and white surfaces react the same way to the infra-red radiation from the dome. The instrument shows long-term stability in calibration and is independent of tilt effects.

(v) Yanichevski pyranometer:

The receiving surface of this pyranometer consists of manganin-constantan strips forming the thermo elements consecutively connected together either in a rectangular checker board form or in a radial pattern. Alternate segments are painted black and white as is done for Black and White Eppley Pyranometer or Schenk Pyranometer. The instrument exhibits large cosine error.

Pyranometers, CM-5 (Moll Gorczynski) and Indian thermoelectric, are presented in more detail elsewhere in this book.

(vi) Photo sensor pyranometers:

The use of photo-detectors considerably reduces the cost of the instrument. They are normally simple, rugged and light in construction. Since the response of photo sensors is very fast to changes in the field, their time constants are quite low and they can be used for study of fine structure of the radiation field. To reduce the deviations from cosine law response, normally the photo detectors are provided with a good diffusing cover which is not opaque to the solar irradiation wavelength ranges. However, the major limitation is the very strong spectral dependence in the output of the photo detectors. Silicon diode is normally

used for this purpose as it has a better stable performance than many other detectors like selenium. It has a peak response at 900nm decreasing to 50 per cent at 400 nm and 1000nm at either end of the spectrum. Thus, use of a silicon diode introduces systematic differences especially due to the varying atmospheric conditions, like water vapour content and dust particles, which drastically affect the spectral characteristics of the incident irradiation. Thus, photosensitive pyranometers are not of comparable accuracy for short duration measurements. Where high accuracy levels are not required, these pyranometers may be used for obtaining daily total global solar irradiances, provided they are calibrated under different climatic conditions, over extended periods of time against a standard thermopile pyranometer. However, they can be used for evaluating photovoltaic systems.

Few of the pyranometers, which are commonly used are shown in **Fig.2.3. Table 2.1** gives a comparative statement on the performance features of select pyranometers.

Bimetallic pyranographs:

Where high accuracy is not a primary requirement, the pyranographs (also called actinographs) may be used, from which the daily totals of global solar irradiance values can be obtained. The uncertainties in the values obtained can often exceed 10 per cent. Pyranographs use a blackened bimetal strip which is fixed at one end. The free end is connected to a pen arm using a chain link and lever arrangement. Due to the solar irradiation, the bimetal strip gets expanded or contracted. Since invar-one of the element in the bimetal- has a low coefficient of expansion, the other element brass/steel expands and causes a curvature in the bimetal strip. This causes the pen arm to move accordingly and the pen attached to it traces a record on the chart wound around a clockwork drum. The area traced on the chart is proportional to the irradiation received during the day. Since the instrument has to respond only by contraction or expansion, the time lag is large-more than 10-15 minutes. Hence, the pyranograph cannot be used for delineation of fine structures in the irradiance field or even for working out the hourly values. The instrument calibration is also highly temperature dependent. To reduce this dependence, two strips identical to the black strip are mounted on both sides of the black strip and firmly fixed at both ends. These two strips respond to the ambient temperature as the black strip does, by expanding or contracting and thus maintain the length of the strips to be equal to that of the black strip. To reduce the heating of the two strips, they are either plated bright or painted with a strongly reflecting white paint.

Pyranograph

Fig 2.3: Pyranometers

In the Fuess model, a white painted plate is mounted below the black strip to prevent the solar heating of the interior. But the reflections from this plate are found to seriously affect the black strips. The Casella make provides the masking plate on level with the black strip, thus reducing the temperature dependence. Two additional bimetal strips, one half in length, mounted vertically in the metallic support to the sensing black strip, provide some compensation to the curvatures arising due to ambient temperatures. In SIAP model, two white strips are not masked and they are mounted on both sides. A temperature correction to the calibration factor is applied, by finding the mean temperature of the day from the temperatures at specified times in the day. All the pyranographs use a hemispherical glass dome to enable the measurement of global solar radiation. There are other models having similar features available for measurements.

Bellani Spherical Pyranometer:

To meet the requirements of agriculture, botany, zoology and biology, the spherical pyranometer has been designed. This records the incident global irradiance as well as that reflected by the surroundings. A glass sphere coated grey with a mixture of metallic oxides is enclosed in a sphere and sealed. The inner sphere has a graduated tube attached to it. A narrow glass tube which is attached to the inner sphere projects to a level up to which the evacuated inner sphere is filled with pure alcohol. On being irradiated, the alcohol evaporates and then the vapour condenses into liquid inside the graduated tube. The amount of alcohol collected in the tube, is a measure of the incident irradiance. The instrument is set after sunset when the temperatures become more steady. Since the container and the alcohol have a considerable thermal capacity, a certain amount of time has to be allowed for steady state conditions. The calibration factor depends on temperature and a correction has to be applied for each temperature range.

However, both bimetallic pyranographs and spherical pyranometers are being phased out by the more reliable thermoelectric pyranometers.

Shading devices for diffuse solar irradiation:

The global solar irradiance is made up of the direct beam solar irradiance and the diffuse solar irradiance. The diffuse component plays an important role in energy exchanges as well as in the human comfort levels. Hence, its measurement is of great importance. Occluding only the sun's beam, will enable measurement of the diffuse component. A shading disc which will subtend 5° at the pyranometer and whose shadow will just cover the glass hemispheres, is an ideal device. For this, the disc has to be designed suitably and

mounted on an equatorially mounted solar tracker, so that the disc will follow the sun and keep the sensor and its glass domes permanently covered. This would necessitate the use of another pyranometer in the same class as the global pyranometer. Though a rotating shading device will shade the sensor for some time, this method is not recommended as the sensor would not have reached the 100 per cent of the true values of either global or diffuse irradiance when the sensor is alternately exposed or shaded.

Thus, on a network scale a shading ring arrangement is normally used. This arrangement again has to have an equatorial mount and a provision for adjustment for the changes in the apparent N-S annual movement of the sun. Such a shading device, however, unnecessarily cuts off the diffuse irradiance from other parts of the sky that is permanently covered by the shading ring. This would thus necessitate the application of a factor to correct for the loss in diffuse irradiance due to the ring in the parts of the sky other than the instant direction of solar beam. The correction factor, however, does not give the required level of correction as the basic assumption of isotropic scattering in the atmosphere is not strictly correct. The anisotropy is strong with the changing cloudy conditions and the changing concentration in the particulate matter.

Fig 2.4 shows some of the different types of shading devices in use.

Pyrradiometers:

Pyrradiometers measure the total radiant energy which is made of the short wave solar irradiance and of the long wave terrestrial radiant energy. One major problem that has to be dealt with is the identification of a sensor which will have a flat response over the very wide range (300nm-50/100 μ m) of the spectrum. There are no absorbers other than thermopiles having a uniform sensitivity over this extended range of wavelengths. Only thermopile based sensors continue to be used for the total radiant energy fluxes. One major source of uncertainties in these measurements is that the sensor does not reach any equilibrium state as it itself is involved in the energy exchanges and is affected by the window material and installation structures which radiate and interact with the sensor at similar temperatures and hence in similar wavelength regions. Thus, the heat losses or gains close to the sensor need a very critical study. Another major effect of this inequilibrium condition is the existence of convective currents close to the sensor region. To minimize this effect, several designs have been employed. Some of the important methods used are:

Shading Disc

Scheupp's shading ring assembly

Eppler shading ring

Kipp and Zonen shading ball

Kipp and Zonen high latitude shading ring

Fig 2.4 – Shading Devices

- (i) Expose the sensor to the atmosphere. Some designs use empirical formulae to be applied for wind effects. Other designs calibrate the instruments under different wind speeds and apply them as corrections during actual measurements. In the long run, dust gets deposited on the sensor surface, seriously affecting the emittance and the absorptance of the surface. With moisture deposits, the dust may form crusts which may become difficult to remove. Any moisture depositions due to rain or dew will also cause cooling of the black surface due to evaporation leading to spurious data. The output of the sensor will, therefore, never be steady.
- (ii) Expose the sensor to the atmosphere and provide ventilation by using air pumping motors to maintain a steady airflow which will swamp the convective effects due to the wind. Though this will reduce the effect of wind, it does not eliminate the effect. Similarly, the effects of dust deposits and rapid cooling due to evaporation of moisture deposits are reduced but not eliminated. If the wind is in a direction perpendicular to the pumped flow, it will result in a very unstable condition.
- (iii) Provide hemispherical windows which will transmit radiant energy both in solar and terrestrial wavelength ranges. This is easily proposed than achieved. Most of the window materials with appropriate transmission properties are crystalline and hygroscopic in nature and they have low value of hardness. Thus, the transmission characteristics of the window material is easily affected, even while cleaning and due to the presence of moisture in the atmosphere. Window materials with sufficient hardness are too costly for regular outdoor use. However, polyethylene is found to have good transmission characteristics but the material is easily affected by solar irradiation and its transmission is quickly reduced due to clouding of the polyethylene material.
- (iv) If the window material of polyethylene is not thin, it is found that the radiant energy is, to some extent, absorbed by the window itself. With deteriorating transmission properties, the output from the sensor is, therefore, not reliable. To reduce this effect, extremely thin polyethylene hemispheres can be used. However, the shape of the hemisphere would not be maintained due to extreme thinness. Normally, this hemispherical shape of the window is maintained by having air circulation at extremely low pressure which is just sufficient to keep it fully inflated. This controlled air circulation also helps in considerably reducing the convection effects.

However, the instruments that use window materials suffer from a major drawback. Whenever a film of water forms over the material due to rain or dew, the sensor instead of receiving the radiant energy from the atmosphere will be subject to the radiant energy effectively emitted by the water film layer. The output of the sensor during this period is, therefore, not representative of the actual radiation field.

Pyrradiometers can be used to receive the downward total radiant energy. In this case the instrument sensor will face upwards. For measuring the upward total radiant energy, it should face downward to the underlying surface. In both cases, however, the sensor, while it receives the total radiant energy, will also be losing radiant energy in the infra-red at its temperature. Thus, in all such measurements a correction for the loss of energy has to be applied. Since the sensors are nearly black bodies due to their optical black coating, the energy lost can be obtained from σT_s^4 where σ is the Stefan - Boltzmann constant and T_s is the temperature of the sensor in degree kelvin. A temperature sensing device like a thermistor or a thermocouple can be embedded at the bottom side of the sensor. Alternatively, a temperature-compensation circuit to heat the surface by a level which will be equal to the radiation lost by the sensor can also be incorporated. With this value (equivalent to σT_s^4) added, the pyrradiometer gives the downward or upward total radiant energy.

When both sides of the sensors are exposed in a horizontal plane, the sensor will receive the downward and upward radiant energy and its output will correspond to the balance between the two, giving the net value of total radiant energy across the instrument. Such instruments are termed net pyrradiometers.

In some cases, it is required that only the terrestrial radiant energy component is measured. This would then require that the sensor is blind to solar irradiation. The pyrradiometer and the net pyrradiometer when used only during the night, will yield the terrestrial radiant energy directly, of course after correcting for the radiation loss from the sensing element. But during the day, the solar irradiation is the more dominating component and hence, it is to be eliminated if the terrestrial radiant energy alone is needed. This is achieved by using a silicone hemispherical dome with a vacuum-deposited interference filter on the interior side of the hemisphere which effectively blocks solar irradiance. Such instruments which measure only terrestrial radiant energy are called pyrgeometers.

Exclusive measurement of downward or upward total radiant energy is not commonly pursued. Most of the available net pyrradiometers can be used for this purpose by shielding the opposite surface appropriately from the radiation. However, the temperature of the sensor has to be monitored separately, so that the loss of terrestrial radiant energy from the sensor can be accounted for.

Beckman and Whitely pyrradiometer is a modified version of Gier and Dunkle design and has a blackened flat-plate sensor containing 720 silver-constantan thermopile.

The side facing away from radiant energy has an aluminum shield highly polished on the outer side and matt black on inner surface which helps in maintaining the temperature of the shielded side of the thermopile. The instrument has no window and the convective currents near the thermopile sensor are kept to the minimum by having a forced air stream supplied by an electric blower housed in the main support of the instrument. This air stream also reduces the amount of dust deposition and prevents dew deposition. The temperature compensation is provided by thermistors which are embedded in the plate. An analogue circuit generates a voltage proportional to the thermal radiant energy lost by the thermopile sensor at its temperature. This is achieved by two thermistors embedded in the thermopile plate and feeding this output through a fixed resistor. The circuit is so designed that the current through the fixed resistor is proportional to the fourth power of the thermopile surface temperature.

Net Pyrradiometers:

Total radiant energy is generally measured by using a net pyrradiometer.

Yanichevski net pyrradiometers:

The Russian model Yanichevski net pyrradiometer does not use any window material or maintain a stream of forced air current across the sensor. The sensor consists of a silver-constantan thermopile arranged in ten sections of copper bars and electrically insulated from the bars. There are 600 thermo junctions with a thin copper foil on both sides again electrically well insulated from the thermopile. The top surfaces are painted matt black. Since the instrument is unprotected, its output and calibration are easily affected by wind field. A correction factor has to be applied depending on the wind speed, the calibration for each instrument being carried out individually under different wind speeds. The black coatings change the colour due to dust deposits. The instrument is normally turned upside down every few days to minimize the rapid changes in the absorptance and, therefore, in the calibration factor. Any moisture deposition due to precipitation or dew drastically changes the output due to the associated rapid cooling caused by evaporation from the surface.

Kew net pyrradiometer:

This is also an unshielded instrument but has an air blower which maintains a steady air stream across the thermopile sensor. The sensor is a 120 junction copper-constantan thermopile covered with thin aluminum sheets which are in good thermal contact but electrically well insulated from the thermopiles. To reduce the wind effects, the instrument is

provided with an air blower housed in a casing at the end of an extended air duct. This extended duct runs along the sides of the sensor plate and reduces the effect of crosswinds. However, the performance of the instrument shows that effects of wind speed and direction cannot be eliminated or even reduced to any insignificant level.

Gier and Dunkle (Beckman and Whitely) net pyrradiometer:

As described earlier, this is also an unshielded and ventilated instrument with both top and bottom surfaces exposed to the radiation field. The main advantage of this instrument is the temperature compensation provided in the output circuit.

Shielded net pyrradiometers:

Almost all shielded net pyrradiometers use polyethylene hemispherical domes, as polyethylene has good transmission characteristics in the entire region of interest, i.e. from about 0.29 to 60 μm except for some narrow absorptions within this region. One major disadvantage in these polyethylene hemispheres is that the material changes transmission characteristics with continued exposure to solar irradiation and gets a clouded appearance. This would necessitate frequent replacement of the domes, in which the quality of the polyethylene has to be maintained the same so as not to affect the calibration factor.

Schulze net pyrradiometers:

A pair of silver-constantan thermopiles is used for each side, one facing up and the other facing down. The two thermopile sets are mounted on a good heat sink to achieve uniform temperature inside the instrument. A six-element thermocouple set embedded in the heat sink provides the temperature of the instrument. Since the two surfaces have individual thermopiles and since the temperature of the instrument is measurable, the instrument can be used for determining the downward total net energy and the upward total net energy independently. When connected together it gives the total net radiant energy flux. When used with a reflected and global pyranometer, all the individual components of radiant energy can be measured/derived. However, a major problem with this version is the possible non-equivalence in the calibration factors between the two surfaces.

A modified make of this pyrradiometer uses a pair of semiconductor thermopile made of 48 thin sheets of Bi-Sn and Sb-Bi alloys bonded between thin sheets of aluminium. The sensing surfaces are coated black. A major advantage of this instrument is the very high output of 90-100 $\mu\text{VW}^{-1}\text{m}^{-2}$ and the low internal resistance of less than 5 ohms. The newer

instruments have provisions for circulating air into the core thick aluminium sink to maintain it at the air temperature. The sensors are shielded by polyethylene (Lupolen H, 0.1mm thick) hemispherical domes fixed to threaded brass rings. However, these domes are found to absorb the thermal radiant fluxes leading to changes in the calibration whenever the hemispherical domes are replaced. To obviate this error, very thin polyethylene hemispherical domes are used by Funk in his net pyrradiometer.

Funk net pyrradiometer:

The sensor has two rows of 125 wire-wound plated copper-constantan thermocouples separated by a sheet of plastic and sandwiched between two electrically insulated thin aluminium plates of 30 x 40 mm in size. The outer foils of aluminium are painted with optical black. The instrument has two window shields made of thin polyethylene hemispherical domes. Since the domes are 0.05mm thin, they have to be kept fully inflated by a very slow stream of dry air/nitrogen. Here too, the domes have to be replaced when the transparency decreases. The sensor is mounted at the centre of a phenol based material arranged in several thin layered sheets. The air ducts which also serve as electrical connectors are embedded in these layers. A ring with heating element around the sensor head can be used to prevent any dew deposits on the hemispheres. Equivalence between the two sides is achieved by covering some part of the thermopile with white paint, which depends on the individual sensor.

Fritschen miniature net pyrradiometer:

This has a 22-junction thermopile of manganin-constantan. Temperature compensated models are also available. The sensor is mounted on a light handle which has provision for mounting hemispherical domes of appropriate size. The space between the domes is filled with dry air through two purge orifices. When the air pressure decreases due to continued exposure, more dry air can be pumped in through the orifices. The instrument can be held by hand for making measurements, especially, in small areas, like 'under a canopy'. **Thorntwaite miniature net pyrradiometer** is also of similar type.

Fig.2.5: Net pyrradiometers

Soumi-Kuhn economical net pyrradiometer:

The net pyrradiometer consists of two circular pieces of expanded polystyrene about 30mm thick and 210mm in diameter. A thin blackened aluminium foil of about 0.006mm thick is fixed at the centre of each of the circular polystyrene heads. A thermistor is attached at the centre of each foil to measure the changes in temperature which are proportional to the radiant flux incident on the foils. Heat conduction between the sensor and the head is minimized by proper insulation. An air space bisected by another aluminium foil is used to minimize the heat transfer between the bottom and the top sensors. A double layer of stretched polyethylene film shields each sensor from the effect of wind. Since the sensor is mounted slightly lower than the circular rim, it does not have the exposure to the entire hemisphere. Normally this instrument is used for determining the vertical profile of the thermal radiation field by attaching it to a radiosonde equipment. Thus, these measurements are restricted to the night time only. During the day-time, errors are likely to occur because of (i) non-horizontal position of the sensors due to the unavoidable swinging of the instrument while ascending, (ii) possible shadow cast by the balloon and the large sky portion obstructed by the balloon and (iii) the stretched polyethylene window, which may get a sag due to the solar heating.

Kipp and Zonen pyrradiometer:

The sensor is made of thermopile, whose output voltage is proportional to the net radiant energy. It has spectral response from 0-100 μ m and does not use hemispherical windows. The detector is based on a teflon coated weather resistant blank conical absorber. Thus the requirements of maintenance care and the uncertainties due to transmission conditions of the hemispherical domes are greatly reduced.

IMD net pyrradiometer is discussed separately later in this chapter. Fig.2.5 shows some of the net pyrradiometers discussed above.

Pyrgometers:

Instruments which measure only the terrestrial radiant energy are called pyrgometers. Measurement of this energy in the night time is not very difficult as the only field available is that of the terrestrial radiant energy. However, during the day-time the solar irradiation is more dominant. If the terrestrial radiant energy during the day is to be measured, the instrument should be solar blind which is difficult to achieve. Very few

instruments are in vogue under this group. Ångström pyrgeometer which is one of the early versions of pyrgeometer and not in use now, except in India, is described in a later section.

Eppley pyrgeometers:

It comprises of a wire wound-plated thermopile detector encased in a chrome brass housing. Temperature compensation circuit as in the case of PSP pyranometer is incorporated in the configuration. To compensate for the radiant energy lost due to emission by the sensor surface at its temperature, a battery voltage which is adjusted by a precision thermistor according to the temperature of the sensor surface, is introduced in the principal electrical circuit. Thus the output is not affected by the differences in the incident and emitted radiant energy fluxes. The thermopile is a 100-junction copper-constantan thermopile with a thin plastic cover over it. A removable KRS-5 hemispherical dome which is transparent to radiant energy even beyond $50\mu\text{m}$, ensures filtering out the solar irradiance. It has a weather protective coating on the outer surface. An interference filter system is vacuum deposited on the inner surface of the hemispherical window allowing the dome to transmit in the desired wavelength range $4\text{--}50\mu\text{m}$. The instrument is meant for continuous field use.

Kipp and Zonen pyrgeometer:

The thermopile detector is provided with a thermistor to measure the internal temperature in an anodized aluminium casing. The window dome of silicone material is provided with a solar blind filter. An outer coating provides protection to the dome from the environment. The dome is not hemispherical but the manufacturer claims a 180° field of view. The pyrgeometer has negligible directional error. The dome is designed to maintain its thermal stability, so that the need for the measurement of the dome temperature is not necessary. A thermistor attached to the detector provides the temperature of the detector. With a controlled battery voltage; necessary compensation can be obtained for the radiation losses from the sensing surface. Ventilation arrangements are also available, if required, which will help in maintaining the instrument at the ambient temperature.

Measurement of UV irradiances:

Designing an instrument for measuring ultraviolet is a challenging problem, because of the very low energy levels to be measured and the filtering out the remaining parts of the solar spectrum, viz. visible and infra-red regions where the energy levels are very high. The filters, mostly interference type, have to absorb the higher irradiances. These filters are,

therefore, subject to heavy dosages of irradiances and in addition they are to withstand the thermal shocks due to passing clouds. Thus the stability of the transmission characteristics of the filters and consequently the calibration of the instrument have to be checked as frequently as possible. UV radiometers in general use in meteorological networks are of three types - (i) Total UV (280 – 400nm), (ii) UV-A (315 -400nm) and (iii) UV-B (280 – 315nm)

(i) Total UV radiometers:

Eppley Make:

A hermetically sealed selenium barrier-layer cell is used as the sensor for the UV range 295-385 nm. The cell is protected by a quartz window. An encapsulated narrow band pass interference filter limits the spectral response to 295-385 nm. The entire system is enclosed in a brass tube. The instrument is installed to look at the zenith and is provided with a teflon diffusing cover. This reduces the strong solar irradiance to acceptable levels and also provides close adherence to the Lambert cosine law. A calibrating lamp system is available to periodically check the calibration of the radiometer. The linearity of output is generally within 2%.

(ii) UV-A radiometers:

Kipp and Zonen broadband CUV-3 radiometer:

UV-A measurements are also in the broadband ranges. The choice of filter with transmissions from 320-385 nm ensures UV-A irradiances being measured. The sensor is a photodiode used in combination with a UV filter and a diffuser. The diffuser ensures correct angular response. The voltage output of the photodiode is made to be linearly proportional to the solar UV irradiance. The sensor unit is mounted in the same pyranometer body. The filter has spectral transmission range from 320 nm to 400 nm. The output signal has a range of 0-40 mV under normal conditions. The linearity of output is generally within 1%.

(iii) UV-B radiometers:

UV-B ranges are physiologically important because it includes erythral wavelengths which have destructive actions on organisms and which destroys the skin tissues. UV-B radiometer like Robertson-Berger radiometer filters out nearly all visible wave-lengths using UV-transmitting blocking filters. The UV radiation then strikes a UV-sensitive phosphor which emits fluorescent radiation in 400-600 nm. Another band pass filter removes all other wavelengths outside 400-600 nm range and the resultant irradiance is

measured using a gallium arsenic or a gallium arsenic phosphorus photodiode. Robertson-Berger instrument uses a photomultiplier tube to measure the output signal. The quality of the instrument depends on the protective quartz cover, the cosine response, the temperature dependence and the matching of the erythral curve with the spectral sensitivity of the instrument.

Dehne used a set of interference filters and a photomultiplier tube in his design. This instrument also uses a quartz diffuser. However, the irradiance in these wavelengths is quite low and hence the photomultiplier tube has to be carefully chosen, keeping in view the stability requirements. Spectral measurements in the UV-B region are made using interference filters at the standard wavelengths of 305, 310, 315 and 325 nm. Narrow bandwidth with 2nm full-width half-maximum is recommended. The sensors use one or more interference filters. The simplest instrument consists of a single filter, say for 305 nm and a good quality UV-enhanced photodiode. The out of band rejection for such filters have to be better than 10^{-5} . To maintain a constant temperature, peltier cooling at 20°C is used. Or the temperature can be maintained near 40°C well above the ambient temperature. The interference filters, however, deteriorate faster at these higher temperatures. If a photomultiplier tube is used, more accurate measurements even at very low irradiances are possible. In case more than one spectral range is to be used, a photomultiplier tube with 3-4 interference filters for the desired wavelengths mounted on a filter wheel may meet the requirement.

To avoid wavelength shifts due to tilt of the surface to the incident irradiation, the measurements are made using the radiometer in the form of a pyrhelimeter by mounting it on a solar tracker.

With the advent of monochromatic gratings, spectral separation using single or double monochromators, is carried out efficiently and the incident irradiance is measured using photomultiplier tubes with appropriate electronics. Motor driven scanning methods enable serial spectral measurements within the desired spectral ranges. The irradiance is incident on a teflon cosine diffuser. The bandwidth is normally about 1 nm with the central wavelength lying within 0.2 nm of its nominal value. Stray light cut-off is quite high (better than 10^{-8}). Sampling can be done at every 2nm interval. Optronics Laboratories Inc., USA; EKO Instruments Trading Co. Ltd., Japan; International Light Inc, USA and Laser Optronics Ltd., USA are some of the manufacturers of UV spectroradiometers using grating technology.

Brewer Spectrophotometer is such an equipment basically made for ozone measurements. It also measures irradiances in UV (286-363nm) and in the visible (430-450 nm) regions. The Brewer spectrophotometer contains an Ebert spectrometer having a holographic reflecting diffraction grating. The optical entrance system directs the light through an entrance slit and the grating disperses the irradiance into high quality spectrum with a spectral resolution of 0.6 nm in UV and 1nm in the visible. Six slits for specific wavelengths are optically positioned and they allow the selected irradiance to be incident on a low-noise photomultiplier detector. The operations are all done by computer controlled electronic devices with microprocessors. Raw data is recorded on hard disc drive and the data can also be downloaded when needed. A UV dome assembly using a thin teflon for cosine correction enables the Brewer to measure the global UV irradiances. The Brewer assembly is provided with solar tracking devices having necessary software controls. This enables the instrument to be oriented to the sun throughout the day. The instrument is highly reliable and accurate over a wide range of ambient temperatures and humidity conditions.

Sunshine Recorders:

The term sunshine is normally associated with the energy received from the sun in the visible part of the spectrum when it exceeds the background diffuse sky light. The meteorological requirement for sunshine is primarily for relating to climatological cloudiness conditions. The sunshine data are also used to characterize the climate of sites, especially of the health resorts and of places of tourist interest. An indirect use is the study of the psychological effects of strong solar light on human health and his living environment. The sunshine duration data are also used as an input in studies concerning agriculture.

The Campbell-Stokes sunshine recorder has been in use for more than a century. Since the manufacturer had different types of sunshine recorders of differing characteristics, there was no common basis for relating the sunshine duration hours obtained by different users. WMO had to step in and conduct an intercomparison of different sunshine recorders with internationally agreed interim reference sunshine recorders. This resulted in the definition of sunshine duration. It is defined as the sum of that subperiods for which the direct solar irradiances exceed 120 Wm^{-2} (using a pyrhelimeter). The units used are seconds or hours. Hours of sunshine are measured with an uncertainty of ± 0.1 hour. A cloudless day has uncertainties at the times of sunrise and sunset due to the low irradiance levels. On a cloudy sky, the uncertainties increase due to the lag in response of the instrumental set-up.

There are different methods by which sunshine duration can be recorded.

- (a) **Burn method:** A spherical glass lens focuses the irradiation on to a good quality pasteboard card and the card gets burnt due to the concentrated solar beam. The burn stops immediately after the sun's disc is occluded by clouds.
- (b) **Pyrheliometer method:** A pyrheliometer mounted on a solar tracker gives the irradiance. Electronic or computer controlled discriminators and a time counting device enable the integration of the duration for which the irradiance level is above the threshold value of 120 Wm^{-2} .
- (c) **Pyranometric method:** A global and a diffuse pyranometer used side-by-side give the direct irradiance values taking the solar elevation into account. A discriminating device and a time counter enable the sunshine duration to be integrated whenever the threshold of direct irradiance is above 120 Wm^{-2} .
- (d) **Contrast method:** Generally photovoltaic sensors in different positions discriminate the irradiation contrasts and the output signals are contrasted to arrive at a value which will correspond to the threshold value.

Foster sunshine switch consists of a pair of selenium cells, one of which is exposed to the sun and the other shielded by a shadow band. The cells are connected in such a way that there is no signal output when there is no direct sunbeam. The switch is activated when there is irradiation exceeding a threshold level (85 Wm^{-2} in this case). The position of the shading ring needs adjustments only when the seasonal changes in the sun's apparent path take place.

In **Haenni model**, six silicon solar cells connected in series are used to obtain the signal output due to solar irradiance. A screening device having 12 rps rotation, shields a set of cells exposing the other cells to the sun's beam. The differential output from the detector is used to give the sunshine when used with a discriminator and a time counter. When there is no sunshine, there is no output from the cells due to same diffuse irradiance levels.

- e) **Scanning method:** Discrimination of solar irradiance from continuously scanned small sector of the sky, triggers a discriminating device and runs the time counter. The detector normally has only one sensor receiver.

However, since the selenium cells and silicon photocells have strong spectral response and the characteristics of the small hemispherical dome protecting them are different, the sunshine duration obtained with reference pyrheliometric methods will show

considerable differences. The cloud distribution near the sun can also cause deviation due to strong reflections.

The burn method does not require much critical maintenance. However, daily replacing the used card by a new one and the possible errors in manual evaluation of recorded data are possible shortcomings in this method. Whereas the other methods offer better sunshine duration data, they need proper routine checks to ensure reliability in the derived data.

Instruments in use in Indian (IMD) Network:

India Meteorological Department (IMD) has been measuring radiation parameters at different stations since 1957. A brief description of the various radiation instruments in use in the network is given in the following paragraphs.

Ångström Compensation Pyrheliometer:

This is an instrument belonging to a secondary standard category of pyrheliometers, capable of a high accuracy of 0.5%. The instrument's sensor consists of two thin blackened manganin strips 0.02 mm thick, 2 mm wide and 20 mm long. They are mounted in parallel and side by side on a bakelite mount. Attached to each of them is a copper-constantan thermocouple. They are connected in series. They are in good thermal contact with the manganin strips but are well insulated from them electrically. The mount is fixed at one end of a 230mm long brightly plated brass tube. The other end of the tube carries a circular brass diaphragm having a rectangular opening and a moveable shutter. Two more diaphragms below this restrict the field of view to 5.1° in the vertical and 2.6° in the horizontal. The tube is mounted on a tripod stand with worm and gear arrangement to rotate the tube both in horizontal and elevation planes in order to adjust it to face the sun. A sighting device attached to the side of the tube enables the adjustments for the normal incidence of the irradiation on the strips.

In practice, one of the strips is shaded by the shutter giving rise to a difference in the temperatures of the two strips. This is sensed by the thermocouples attached to the strips and the thermo emf generated causes a deflection in a very sensitive galvanometer or a null detector. An electric current is then passed through the shaded strip to heat it to the same temperature as that of the exposed strip. When the rate of heating by irradiance becomes equal to that by electrical heating (indicated by the deflection coming to its original zero value), the solar irradiance is proportional to the square of the current, the absorptance of

the black surface and its electrical resistance. The electrical current needed to heat the shaded strip to obtain the thermal equivalence between the two strips is measured on an accurate and sensitive milliammeter. The adjustment of this current is carried out by using a variable resistor unit and a voltage source (power supply unit).

In actual measurements the two strips are alternately exposed (heating the shaded strip electrically) three or more times and the mean current is determined. If i_R is the balancing current obtained when the right strip is irradiated and i_L is that when the left strip is irradiated, then the irradiance S is given by $S = K (i_R + i_L)$ where K is the calibration factor which accounts for absorptance, electrical resistances of the strips and their dimensions. This calibration factor is determined by comparison with a primary standard and not from the first principles. When the measurement is restricted to three exposures only, i.e. the right strip two times and the left once only or vice versa, then the irradiances S is obtained from-

$$S = K i^2$$

where i is given by

$$i = \frac{i_{R1} + 2i_L + i_{R2}}{4} \quad \text{expressed in amperes}$$

A rotatable filter holder having rectangular band pass filters of known wavelength ranges enables the spectral distribution of solar irradiance to be measured.

The following filters are used in India:

Filter Type	Wavelength range (in nm)	Wavelength range (in nm) actually used in India
OG 530 (OG ₁)	526-2900	525-2800
RG 630 (RG ₂)	630-2900	630-2800
RG 700 (RG ₈)	702-2900	710-2700

From the spectral irradiance values using these broadband filters, it is also possible to derive the spectral irradiances in the various broad spectral ranges and also to work out the “turbidity factor” and the “Ångström turbidity coefficient β ”. These are outlined in Chapter VII of this Handbook.

Thermoelectric Pyrheliometer:

The sensor used in the network is a wire wound copper-constantan thermopile covered with thin aluminium foils to act as the receiving surface. The side which is to receive the irradiance is coated with optical black paint. The thermopile is embedded on a good heat sink made of thick brass cylinder 39 mm in diameter and 70 mm in length. The cylinder

is mounted on a tufnol cover. The whole assembly is mounted at one end of a 30 cm long and brightly plated brass tube. A series of 5 diaphragms limits the field of view to a 5° opening angle and a slope angle of 1° . A sighting device provided on two 120 mm circular plates enables the orientation of the pyrhelimeter to the sun. The pyrhelimeter is designed for continuous measurements and hence it is provided with an optically true glass window with uniform transmission in the 290-4000 nm wavelength range. The pyrhelimeter is mounted on a two axis solar tracker and continuous recordings are obtained on a potentiometric recorder or the data logged by a data logger. The Indian thermopile pyrhelimeter has a time constant of 25s for 95% response and a sensitivity of $5-8 \mu\text{VW}^{-1}\text{m}^{-2}$. The spectral response is flat within $\pm 0.2\%$ and the non-linearity is within $\pm 0.5\%$. From the irradiance values obtained, not only the diurnal variations in the solar irradiances but the variations in the “turbidity factor” can also be monitored.

Sunphotometer:

As mentioned in Chapter I, sunphotometers are used for the quick estimation of the atmospheric optical depth and to study the trend in their values at a place. Till recently, the network instrument in use was a Volz type sunphotometer. This sunphotometer consists of a small wooden box with an aperture of 4.5 mm in diameter giving an opening angle of 3° at the sensor. Behind the aperture is a gelatin narrow band pass filter centred at 500 nm wavelength and with a bandwidth of 60 nm. When the sunphotometer is held in hand at normal incidence to the sun's rays the irradiance gets filtered by the filter and irradiates a photoelectric selenium cell. The current output in microamperes is measured by an analog microammeter. The variations in the output are direct indicators of the atmospheric optical depth. A diopter scale graduated in terms of optical air mass gives the value of the airmass at the time of measurement. This is obtained by holding the instrument horizontally (checked with an attached spirit level) and adjusting the diopter scale to be perpendicular to the irradiation with the help of the sighting device provided on the scale. The calibration should be done very frequently due to the changing transmission characteristics of the gelatin filter and the changes in the selenium cell output. The calibration is carried out by the Langley method. This sunphotometer is being replaced by the multispectral Microtops Sunphotometer (Solar Light make).

Pyranometer

Moll-Gorczyński Pyranometer (M.G.) (Kipp and Zonen)

To begin with, the network used M.G. pyranometers made by Kipp and Zonen for global and diffuse solar irradiation measurements. The rectangular sensor is made of 14 alternate strips of manganin and constantan ($5 \times 1 \times 0.005$ mm) joined at the centre and supported by massive copper posts at both ends. The central contact points serve as the hot junctions while the edges which conduct the heat to the posts act as cold junctions. Since the strips are arranged close to each other, there is no flat receiving surface like that of an aluminium or silver foil. The entire area is painted with optical black (Parson's optical black lacquer with 98% absorptance in the spectral range 290 nm to 3000 nm). The sensor base is again mounted on a thick threaded metal ring which is fixed inside a plated brass cylindrical tube. This tube is itself in good contact with a massive brass (or gun metal) base, thus ensuring that the temperature of cold junctions is at the ambient temperature. The electrical leads of the thermopile are taken out through copper connectors embedded in glass and fixed to a brass plate which serves as the cover to the cylindrical tube and is held in position by a threaded and plated retaining brass ring. Since a pyranometer is to measure only the solar irradiances in the range 290 nm to 3000 nm, two concentric hemispherical and polished glass domes of 30 mm and 50 mm (inner) diameters are used to transmit the required spectral range and cut off the remaining parts of the spectrum. The domes are mounted on appropriately threaded and brightly polished brass rings. They also protect the sensor from wind, rain and dust. The inner dome prevents the variations in the thermal radiant energy caused by the convections set up by the winds on the outer 50mm dome. The whole instrument is covered at the top by a coplanar protective circular guard plate which prevents the direct heating of the instrument. A tube at the bottom of the instrument allows a desiccator with dry silica gel to be connected to the interior parts to keep them free of moisture. Should any moisture form on the inner surfaces of the glass hemispheres, in spite of the desiccating agent, the domes can be removed using the threaded ring mounts, cleaned and put back. A sensitive circular spirit level permits the instrument to be exactly horizontal, using levelling screws attached to the base of the instrument.

The output of the instrument (in millivolts) is proportional to the irradiance level. It is a differential output based on the temperatures of the hot junctions and the cold junctions which are at the ambient temperature. The time constant for 95% response is about 18 seconds. Since the sensor is rectangular in shape, the longer side is kept in the N-S orientation to minimize errors in cosine response. This error is generally less than 1% for

incidence angles of less than 75° . Care has to be taken for the depression of zero in the extraction of data. This shift is caused mainly by the delayed cooling of the inner dome.

The output of the pyranometer is fed to a galvanometric or potentiometric recorder and the data extracted from the recorded charts. Suitable data logging systems compatible with computers are being brought into use in the network.

Thermoelectric Pyranometer:

Thermoelectric pyranometer developed by India Meteorological Department uses a wire wound plated copper-constantan thermopile. Constantan wire of 0.193 mm in diameter is wound toroidally on a former which is an acrylic disc (perspex) of 19 mm in diameter and 4mm thick. One-half of each constantan turn of the wire is electroplated with copper. The points where the copper and constantan meet, form the thermojunctions on the middle line on both sides of the windings on the perspex disc. Thin aluminium foils are pasted on to the flat surface using a thin layer of epoxy cementing compound over the thermo junctions, so that they are in good thermal contact, but well insulated electrically. These enable the receiving surface, to be plane for the incident irradiation, thus ensuring uniform conduction of heat. The wire-wound former is mounted on a flat brass disc which serves as a heat sink, and then mounted on the same mounting arrangement of the MG pyranometer. The top surface is then painted with an optical black which has a uniform absorption of better than 98% in the wavelengths of solar irradiation. The massive metallic body, which is painted white enables the maintenance of the temperature at the ambient level. The sensor is protected from wind, dust and rain by the use of two highly polished hemispherical domes 30 mm and 50 mm in diameter. The temperature difference between the hot and the cold junctions gives rise to a thermo emf output which can be recorded on a recorder or by a data logger. The output is proportional to the incident solar irradiation.

The pyranometer gives an output of the order of 8 mV and has a resolution of about 5 Wm^{-2} . The cosine error is of the order of 2% up to an angle of incidence of 75° . The response time is, however, large and of the order of 20 s.

Bimetallic pyranograph:

The Indian network uses the bimetallic pyranographs only at two or three locations. The pyranograph is of Robitzsch type and is based on the SIAP model (Italian). The receiving surface is made of three identical bimetal (invar and steel) strips of size 77 x 15 x 1mm. The strips are mounted coplanar and side-by-side. The central strip is painted with

optical black and the other two are painted white with magnesium oxide or titanium oxide, which have high reflectivity. The three strips are fixed to a brass rod by screws at one end. The other ends of the white strips are screwed to a similar brass strip which is, in turn, fixed firmly to a vertical metallic pillar attached to the cast metal base. The black-coated strip is kept free at this end and connected to a simple lever mechanism carrying a pen arm through a fine link chain. The pen arm spindle is held in bearings on two vertical pillars. To keep the pen in balance, a counter weight is attached at its rear end. A fine adjusting screw attached on the brass strip helps to ensure perfect horizontality of the three strips.

Depending on the irradiance levels, the black bimetal strip shows a curvature due to differential expansion of its individual metals. This is conveyed to the pen arm which moves across an appropriate chart wrapped around a clockwork and gives a trace according to irradiance values. The white strips strongly reflect the irradiation and remains at ambient temperatures. The ink in the pen traces the record of the variations in the curvature that occur due to changing irradiance values.

The clockwork with its drum is mounted on the base by means of a nut. The appropriate chart is wrapped over the drum and held in position by a clip. The recorded chart is removed daily after sunset and fresh one put in place. The area of the curve bounded by the time axis is proportional to the total amount of irradiance received over a known time. Since the movement of pen depends on the relative curvature shapes due to elongation or contraction caused by solar irradiance, the instrument shows considerable time lag with changing irradiance levels. Hence the pyranograph is used only for obtaining the daily total irradiance. The bimetal sensors are covered by a well-polished clear glass hemisphere of 110 mm in diameter. This ensures the transmission of solar irradiation only and protects the sensors from dust, moisture depositions and wind. The space between the strips and the base of the glass domes is covered by a highly polished metallic plate to prevent direct heating of the interior of the pyranograph by the sun's rays. To prevent moisture collection inside the instrument, a container with a desiccating agent (silica gel) is provided. Although the white strips are to provide some temperature compensation, the instrument is subject to errors due to variations in ambient temperature. Even the calibration factor varies with temperature and, therefore, a correction is to be applied to it on daily basis. Because of the large uncertainties in the irradiance values, pyranographs are being replaced by thermoelectric pyranometers.

Bellani Spherical Pyranometer:

This instrument working on the principle of distillation of vapour caused by the incident solar heating has already been described on page 39.

Diffuse Pyranometer:

The measuring instrument uses a thermoelectric pyranometer. The sensing surface is permanently kept shaded from the sun's rays to obtain the diffuse solar irradiances. In India, the shading disc mounted on a solar tracking device is not being used. A Schüepp model shadow band device which is fixed at a position on a given day, keeps the sensor under shade from sunrise to sunset. The shading ring (band) arrangement basically has a rectangular angle frame of size 350 mm x 800 mm. To the shorter sides of the frame are attached two angle arms, 700 mm in length with slots along its length. In these slots, sliders carrying a semicircular shadow ring (band) are mounted, so that the position of the ring can be appropriately adjusted to cast shadow on the pyranometer sensor, by moving the sliders in tandem. Also attached to these two angular frames are two brass scales graduated in terms of solar declination from $+24^\circ$ through 0° to -24° . The shadow ring, 51 mm broad, is bent into a semicircular shape of radius 450 mm and held in position by the sliders. The shading ring is painted white on the outer side to reflect the solar irradiation and the inner side which faces the sensor is painted matt black to prevent any energy from being reflected on to the sensor. The pyranometer is mounted at the centre of the rectangular frame which is installed in the exact E-W orientation. The angular frames which are in the true N-S direction are adjusted to be inclined at an angle corresponding to the latitude of the site. The end of the angular arm which projects above the horizontal main frame due to the latitudinal adjustment is to face the North. The sliders are adjusted daily, so that their central part as indicated by a pointer corresponds to the declination of the sun on the specific day.

The sun makes the apparent transit across the sky during the day and hence only a specific part of the ring is useful to block the sun's rays at any given instant. The remaining parts of the ring unnecessarily block the diffuse solar irradiation from other parts of the sky. Hence a correction is to be applied to bring the recorded values to the true values of diffuse irradiation. These correction factors are calculated at the controlling laboratory and provided to the network stations for day-to-day applications.

Pyranometer for reflected solar irradiation

The reflected irradiance measurements are made over the ground with good unobstructed exposure conditions to ensure that they are representative of the surrounding area. Albedometers of different makes in use for this purpose have two pyranometer sensor elements mounted on the same metal frame, one pyranometer facing up and the other facing down. However, in India, two pyranometers are independently mounted, the global pyranometer at an elevated mount and the other in the field at about 1.5 m above the ground. To get the true values for the location, the bottom soil surface is generally kept bare, free from all vegetations. The 'reflected' pyranometer is mounted on two GI plates separated by about 50 mm, so that the heat on the top plate is not easily conducted to the pyranometer base. The plates are slightly larger than the pyranometer base to ensure that no direct solar beam illuminates the pyranometer. In addition, the pyranometer is covered by a cylindrical metallic drum open at both ends to prevent the pyranometer from being affected by rain, dust and winds. Perforated holes in the cylinder ensure that the pyranometer is kept airy at ambient temperature by free passage of atmospheric air inside the cylindrical space. A container having a desiccator (silica gel) is connected to the pyranometer through a long tube. The entire assembly is fixed to an L-shaped angle-iron stand embedded in concrete and the soil. The horizontal limb of the stand is kept facing South, so that the pyranometer also faces South for measurements. The output of the pyranometer is fed to a recorder or a data logger. The ratio of the irradiances received by the two pyranometers gives the albedo of the underlying surface.

Ångström Pyrgeometer:

Unlike other types of pyrgeometers, Ångström pyrgeometer can be used only for instantaneous measurements and during the night time only. The instrument does not use any window material. The instrument consists of two pairs of manganin strips, 30 mm x 3 mm x 0.02 mm, one pair coated with optical black lacquer and the other brightly gold-plated. The strips are mounted parallelly and coplanar with gilded and blackened strips laid alternately. They are mounted on a bakelite holder which has four brass studs on either side of the central rectangular (20 mm x 16 mm) cut out on the holder. The strips are soldered to the studs, which have screws for making electrical connections. The blackened strips are shorted at one end and similar is the case with gilded strips. To the bottom of each strip is attached a copper-constantan thermocouple which is in good thermal contact but well insulated electrically. The points of contacts, i.e. the strips and the studs and the interior of the pyrgeometer, are covered from direct exposure using a brightly aluminised paper. Thus the effective length of each strip is limited to 20 mm.

When the instrument is exposed upwards in the night, the black strips strongly emit terrestrial radiation at its temperature and also receive the radiant energy from the atmosphere above. With the temperatures near the instrument being higher than that of the atmosphere above, the black strips lose more heat than what they receive from above and thus there is an effective cooling of the black strips. The gilded strips being very bright and since gold has very low absorptance and emittance, they remain almost at the ambient temperature. This difference in the temperature creates a thermo-emf in the thermocouples and causes a strong deflection in a sensitive galvanometer. Now, the black strips are electrically heated (since they are at a lower temperature) so as to bring their temperature to be equal to that of gilded strips which are at the air temperature. The current (measured on a sensitive milliammeter) needed to provide heating and thereby to compensate the heat lost, is a measure of the net thermal (terrestrial) radiant energy. If the compensation current is i amperes, then Ki^2 gives the net terrestrial radiant energy where K is a calibration factor of the pyrgeometer in use. If T is the air temperature in kelvin, then σT^4 gives the upward terrestrial radiant energy where σ is the Stefan-Boltzmann constant. $\sigma T^4 - Ki^2$ will, therefore, give the downward terrestrial radiant energy from the atmosphere.

Since the instrument uses the principle of cooling of the black strips on exposure and of heating of the same strips to obtain thermal balance, it can be used only during the night. Since the instrument has no window material, the measurements are subject to disturbances due to convection currents set up by the prevailing wind field and to the errors due to any moisture deposits. This means that the pyrgeometer cannot be used when there are chances for precipitation or dew formation. Obtaining proper thermal balance is also difficult when there are fast moving clouds. In the Indian network, pyrgeometer measurements are made only at selected stations at 2030 hours IST and at one hour before sunrise.

Net Pyrradiometer:

The Indian network uses the Funk-type net pyrradiometer for measuring total net radiant energy. The sensor is a thermopile of 120 copper-constantan thermo junctions formed by winding thin constantan wire of 0.193 mm in diameter on a clear rectangular acrylic former and copper-plating one-half of each turn of winding, thus giving 60 thermo junctions on each surface. The former is 40 mm square and 10 mm thick and has grooves on two sides in between the two square surfaces. The surfaces are then covered with thin aluminium foils using a good (electrically insulating) cementing compound. This ensures uniform horizontal surface to the incident radiant energy and also uniform conduction of heat to the thermo junctions. The sensor is then mounted on the head of the frame of the net pyrradiometer and painted with optical black.

The head of the frame is made of a phenol-based laminated pieces (e.g. tufnol). The head has two laminates having grooves for two capillary copper tubes which serve as the electrical conductor between the thermopile and the external leads as well as air inlet and outlets. The two laminates are then cemented together with the two capillary tubes in their grooves. One end of each tube opens into the central area of the cemented laminates and the other end protrudes through the cylindrically shaped ends of the head. The sensing blackened thermopile is mounted at the centre and their leads soldered to the capillary tubes. The sensor is protected from wind, dust and moisture deposits by two polythene hemispheres of thickness less than 0.1 mm. These hemispheres are kept in position by two brass retaining rings which mesh well with the threaded outer brass rings, fitted to the laminates by means of screws. The surface of the rings and the thermopile all lie on the same horizontal plane on both sides. A circular spirit level is embedded at one of the sides of the flat shaped part of the head. The electrical leads from the capillary tubes are taken out through an anodized aluminium tube of 13 mm in diameter and 80 cm long, which is attached to the cylindrical end of the head by a screw.

The polythene domes have good transmission characteristics in the entire range from 0.3 to 50 μm except for few narrow absorption bands in between. Since the domes are very thin, they easily collapse from the hemispherical shape. To retain the shape, pumped air after passing it through a desiccator (silica gel), is kept circulating, so that the domes remain just inflated. The air flow is kept equal on both surfaces of the sensor to reduce any chances of relative cooling near the surfaces. The output of the instrument is generally of the order of 25 to 30 $\mu\text{VW}^{-1}\text{m}^{-2}$. The temperature dependence is of the order of ± 2 per cent and cosine response is of the order of ± 5 per cent. The time taken by the instrument for 95 per cent response is of the order of 60 seconds.

Normally the net pyrradiometer is installed near the surface at a height about 1-2 m on an L-shaped angle-iron stand. Care has to be taken that the sensor is as far away as possible from the stand to ensure that the stand itself does not become an obstruction and cast shadow underneath. The air pump should be in a separate mount, so that the vibrations due to the pump do not cause vibrations on the net pyrradiometer.

Radiometersonde:

A radiometesonde is an instrument used to measure the vertical distribution of radiation parameters. The sensor is normally attached to a balloon and released. While measurements of solar irradiances have been made using balloon borne radiometers, there are some serious problems, such as the shadow cast on the sensor by the balloon itself, the

reduction in the diffuse irradiance due to the sky portion cut off by the balloon and most importantly, the non-horizontality of the sensor as the balloon rises and swings in the wind. Even use of gimbal mountings will not eliminate this error. Thus the vertical distribution of radiant energy is generally restricted to the terrestrial radiant energy levels, that too during the night times.

The Indian radiometersonde is based on Soumi-Kuhn economic radiometer. This consists of one upward facing blackened sensor and another sensor facing downward. The temperatures of these sensors are measured by means of rod thermistors which are fixed at the centre of two good insulating, expanded polystyrene (thermocol) materials and covered by thin aluminized mylar sheets. The thermistors are in good thermal contact with the mylar sheets but are well insulated electrically. The aluminized mylar is coated with optical black. The resistance of the rod thermistors is of the order of 5-10 k Ω at room temperature and decreases exponentially as the temperature increases. Both the blackened surfaces pasted to the two heads are covered by thin polyethylene films which not only protect the surface from moisture and effects of wind, but also act as an optical window for the infra-red (thermal) radiant energy. These films are held taut on wooden circular frames and tightly fitted to the heads. The polystyrene sheet in between the heads helps in preventing the quick conduction of heat between the heads. The thermistors are connected to the terminals attached to the outer side of the radiometer head. The radiometer measures the downward and upward terrestrial radiant energies measured individually.

The radiometer head is attached to conventional audio modulated radiosonde equipment. The radiosonde used with the radiometer head measures air temperature with another rod thermistor, humidity using lithium chloride hygistor and pressure with a baroswitch having an aneroid capsule. An electronic switch serially connects the transmitter to each sensing element. A ground equipment receives the individual signals and produces a trace on a recorder. However, direct computations are being carried out using dedicated computers for radiosonde works. For the extraction of data, the base check frequencies and their corresponding actual values of temperatures and pressure are noted on the record. Values corresponding to every minute are marked on the record. The frequencies corresponding to the thermistors for the top and bottom surfaces and for air temperature, the reference and the hygistor for every 50 hPa level from surface level, are picked out up to 200 hPa and then for every 25 hPa level.

From the values of the top and the bottom sensors and air temperature, the radiant energy values (E) are derived using the following relations:

$$\begin{aligned}
E_{\uparrow} &= \sigma T_b^4 + \lambda (dT_b/dt) C_i - C_b, \\
E_{\downarrow} &= \sigma T_t^4 + \lambda (dT_t/dt) C_i - C_t \text{ and} \\
E_i^* &= E_{\uparrow} - E_{\downarrow}
\end{aligned}$$

Where, σ = the Stefan-Boltzmann's constant ($5.6697 \times 10^{-8} \text{ Wm}^{-2} \text{ degree}^{-4}$).
 E_{\uparrow} = is the upward terrestrial radiant energy from the surface.
 E_{\downarrow} = the downward terrestrial radiant energy.
 E_i^* = the net terrestrial radiant energy.
 T_b = the temperature of the bottom surface in kelvin.
 T_t = the temperature of the top surface in kelvin.
 λ = 0.01015; the product of effective specific heat and effective mass per unit area of thermistor-mylar combination.
 C_i = the thermal energy transfer from bottom surface upward.
 C_b = the thermal energy transfer to the bottom surface from its polyethylene cover
 C_t = the thermal energy transfer to the top surface from its polyethylene cover.

The correction factors C_i , C_b and C_t depend on the three temperatures which are measured.

The radiometersonde measurements are made in India once in a fortnight, after sunset, at selected locations.

Sunshine Recorder:

The India network uses the tropical model of Campbell-Stokes sunshine recorder. This consists of an optically clear glass sphere, with a refractive index of 1.512, mounted concentrically in a section of a metallic spherical bowl. The sphere has a diameter of 100 mm and is held in position inside the bowl by means of brass screws fitting into cup-shaped attachment. The radius of the bowl is 72.8 mm, so that the sun's rays get focused sharply on a card held in grooves in the bowl. The focal length of the glass sphere is 75 mm. Three overlapping pairs of grooves are provided in the bowl for three cards of different shapes suitable for different seasons of the year. A semi-circular brass bar of nearly rectangular cross section is attached to the back of the bowl as support to the bowl and the glass sphere. The bowl can be moved on the support to adjust its tilt to correspond to the latitude of the place and then clamped in position by means of two retaining screws. The entire set-up is mounted on a heavy 20 cm square marble base. The shorter side of bowl is oriented in

the exact NS direction while installing, with the elevated end of the bowl (due to latitude adjustments) facing the true geographic North.

The recording card (sunshine card) is made from good quality pasteboard, coloured with a matt finish blue ink to ensure good contrast with the burns. The focused sunrays burn and char the card. The burning effect ceases the moment the sun is covered by clouds. When the irradiance level of the sunrays is feeble, the card gets lightly charred or discoloured. White hour lines are printed on the card at right angles to the long edges and symmetrically placed about the central noon mark. The cross marks on the cards indicate points on the central line of the card.

The time is printed in terms of hours and corresponds to the true solar timing (TST). The total length of all burnings-full burns, charrings or discolouration gives the duration of the time during which the sun was shining, i.e. it gives the duration of sunshine on a given day. Four holes in the bowl provide outlet for any water collection during a rainy spell. The wet card normally changes in thickness and care is to be taken while removing the recorded card after sunset. The burnings also leave resins on the bowl which makes the card stick to the bowl. Regular cleaning helps in keeping the bowl free of such obstructions.

The sunshine recorder once properly installed does not require much maintenance except for routine cleaning with a non-greasy clean cloth. There are several instructions on the extraction of data from the recorded card and these are strictly followed at each network station.

Very High Resolution Radiometer onboard INSAT Satellite for Meteorological Observations: *(Input by R. C. Bhatia)*

Functional Description:

The Very High Resolution Radiometer (VHRR), designed to carry out meteorological observations in the visible (0.55-0.75 μm), thermal infra-red (IR) (10.5-12.5 μm) and water vapour (WV) (5.7-6.1 μm) bands, is one of the major payloads on-board INSAT series of our national satellites. The primary application of the VHRR is to monitor developing and moving weather patterns and to measure wind velocity at various levels in the atmosphere. INSAT being a geostationary satellite offers a vantage platform for continuously carrying out these observations. The ground resolution of VHRR at the sub-satellite point is 2 km x 2 km in the visible, 8 km x 8 km in the IR and 8 km x 8 km in the water-vapour (WV) bands. It has the following three modes of operation providing a trade off between the frequency of observation and the extent of earth coverage:

- Full frame mode scans 20 degrees X 20 degrees minimum, in about 33 minutes, covering the entire earth disc and some space around.
- Normal mode covering 14 degrees x 20 degrees minimum E-W in about 23 minutes.
- Sector mode in which the sector can be positioned anywhere in steps of 0.5 degree in N-S direction to cover 4.5 degrees x 20 degrees minimum. E-W is particularly suited for rapid, repetitive coverage during severe weather conditions like cyclones. Imaging each sector takes approximately 7 minutes.

As the earth subtends only 17.5 degrees at geostationary altitude, the 20 degrees coverage in E-W direction for all scan modes ensures cold space view at both the ends of the scan line. This is used for DC restoration and as a calibration point for IR and visible channels.

Payload Architecture:

Fig. 2.7 gives a simplified block schematic of the VHRR instrument. Incoming radiation is reflected onto a 203 mm (an eight inch) aperture R-C telescope by a beryllium scan mirror mounted at 45 degrees to the optical axis. The output beam from the telescope is directed onto a dichroic beam-splitter which transmits visible light energy and reflects IR energy, so that the radiation from the earth is channelled to visible and IR focal planes simultaneously. The detector configuration consists of redundant staggered arrays of four silicon

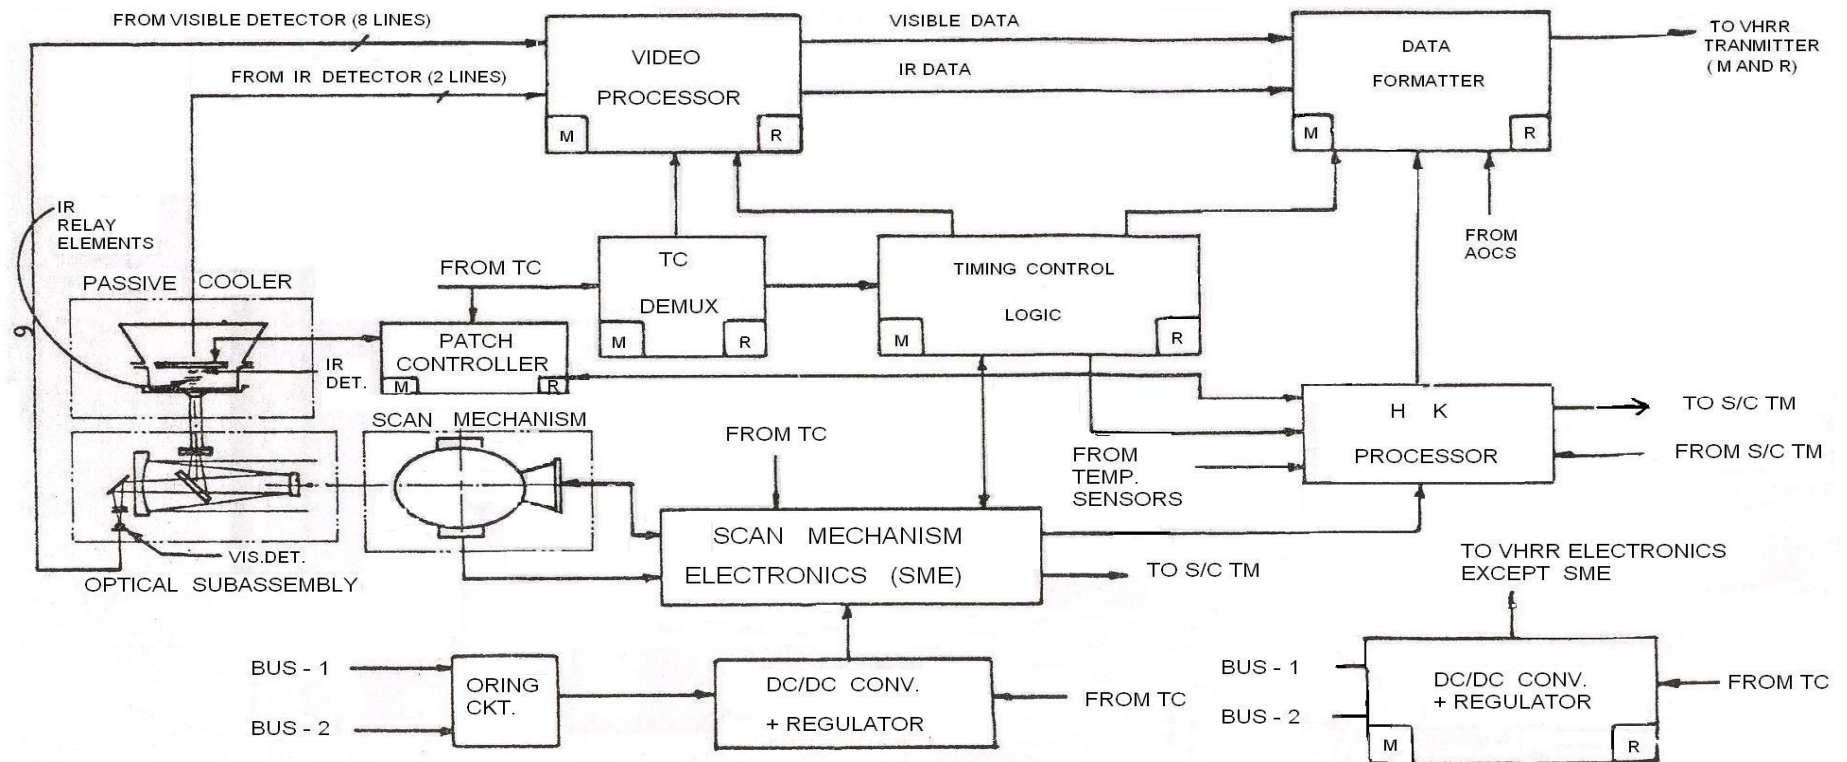

Fig. 2.7: - Insat - 2 Vhrr - Simplified Block Schematic

photodiodes each, sensing in the visible band and redundant mercury-cadmium-telluride detectors operating at 105 K sensing in thermal – IR region. The IR detectors are cooled by a passive radiant cooler. The scan mirror is mounted on a two-axes gimbaled scan mechanism system to generate a two-dimensional image, by sweeping the detector instantaneous field of view across the earth's surface in East to West (fast scan) and North to South (slow scan) directions. Four contiguous visible lines along with a registered IR and water vapour (WV) line are generated during the fast scan at the end of which the scan mechanism steps in N-S direction by one IR instantaneous field of view (IFOV). Scan direction in fast scan is reversed at the end of every line to improve scan efficiency.

The visible, IR and water vapour (WV) outputs are individually amplified, band limited and digitized by ten-bit A/D converters. The digitised data of all the channels, housekeeping information, calibration data etc. are formatted, randomized and transmitted serially in the extended C-band.

The instrument is powered by a DC/AC converter operating from the satellite bus of 42 V and it interfaces with various satellite subsystems for telecommand, telemetry and attitude information.

Exposure requirements for the radiation instruments:

The general requirement for any radiation measurement is that the site should be free from obstructions to the solar beam from sunrise to sunset and for all seasons of the year. It should also be representative of the surrounding area in terrain and vegetation and have a similar environmental condition. Natural objects like hill ranges, distant trees etc. are not considered as obstructions as they are nearly permanent features. In addition, the site of the instrument should be easily accessible for daily routine maintenance work. Under the present day conditions, such sites free of all obstructions, are not generally feasible. The site should, then, be as free as possible from obstructions which may cast well-defined shadows during any time in a year. In the case of pyranometers and net pyrradiometers, the selected site should be away from light-coloured walls and other surfaces to exclude the chance of recording reflected irradiances from these objects. The site should not have any object which will cover a large azimuthal angle and which will subtend an angle of 5° or more at the sensor point. Special care has to be taken to check the elevations of the object that may be within the extreme positions of sunrise and sunset on solstice days, viz. June 22 and December 22. The elevation of all objects should preferably be lower than 5°.

An exposure diagram showing the relative positions of all objects – the azimuthal width a mapping of elevation and azimuthal angles – along with an estimate of distances from the sensor height is generally prepared. A survey camera, a theodolite or compass and a clinometer system may be used to note the azimuth and elevation angles. Based on these, a site plan which will include the exposure diagram and also the relative distances of all objects including the radiation instruments is worked out and maintained. It is once again stressed that the instruments should have easy accessibility for frequent inspections and maintenance care. The recording units - recorders and data loggers - should not be subjected to variations in temperature or mounted on the wall which may get heated from outside due to solar heating. To obtain better exposure conditions, the pyranometers (global and diffuse) are normally mounted on the terraces of buildings. The network stations in India mostly meet these demands.

Data retrieval and archival:

The output of thermoelectric pyrheliometer, pyranometers and net pyrradiometers are normally fed to a recording device. The devices can be galvanometric or potentiometric recorders, integrators or totalisers (with print-out facility on command or at the end of the day's recording) and data loggers with necessary software and compatible with computers.

The Indian network has been using millivolt galvanometric and potentiometric recorders. These are progressively being replaced by the state-of-the art data loggers. The recorders are regularly calibrated whenever the radiation sensors are taken up for calibration, normally once in a year. The galvanometric recorders in the network use daily charts which require replacing the recorded chart by a fresh one in the night time (to avoid any chance of loss of records during the day-time). Depending on the type of potentiometric recorder, the strip charts last generally, for ten days or a month. In either case, time marks at least two times during the day in case of pyrheliometers and pyranometers and two additional time marks during the night in the case of net pyrradiometers are made on the chart, to keep a check on the steady movement of charts.

The data from the recorded charts are evaluated manually at the station itself after applying time corrections for any possible variations in the chart speeds and entered in relevant forms. These data are checked again manually at the station itself. In the case of instantaneous measurements all entries and computations are checked at the station itself. The recorded charts and the evaluated data are sent to the National Climate Centre, Pune for scrutiny and then archival. The data are archived at the National Data Centre on computers and subjected to checks for other possible errors and then stored. The data can

be accessed by users on request and on payment of charges prescribed by the Meteorological Department.

Network Maintenance:

Managing the measurements at network level requires an efficient maintenance schedule. A controlling centre is identified and designated for this responsibility. In India the Central Radiation Laboratory of the Instruments Division of India Meteorological Department at Pune has been designated as the National Radiation Centre and entrusted with the network management responsibility. This Laboratory checks, tests and calibrates all the radiation instruments, mostly made indigenously in the Workshops of the Instruments Division at Pune. It also undertakes installation, periodic calibrations at the field and carries out regular maintenance, analyses and solves problems experienced at the field, replacing the instruments when needed and training the field personnel. Details of calibration procedures required to be followed are given in the following chapter. The radiation scrutiny is carried out at the National Climate Centre in the Office of Additional Director General of Meteorology (Research), India Meteorological Department, Pune. The National Data Centre is also co-located in the same office at Pune. To ensure uniform observational practices and standards, the field personnel are periodically trained at Pune by the experienced scientists of the Central Radiation Laboratory.

NETWORK OF RADIATION STATIONS OF IMD

CHAPTER III

NETWORK OF RADIATION STATIONS OF I.M.D.

Historical Background:

Actinometric measurements were made for the first time at Kolkata as early as November, 1879 though the instruments' details are not clearly indicated. These measurements were continued at Mussoorie from February, 1883 to March, 1887 when the base was shifted to Shimla, and then to Kodaikanal in 1895. More serious measurements were started in 1930 at Pune. In 1930, K.R. Ramanathan used Ångström pyrgeometer for measuring the nocturnal radiation (net terrestrial radiant energy) along with B.N. Desai. Ramanathan also made recordings of direct solar irradiances with an Ångström pyrhelimeter which is even now (2009) in the same good working condition. Later, P.K. Raman, L.A. Ramdas and O. Chacko made hourly observations of night radiation using pyrgeometer and correlated them with atmospheric temperature and humidity. However, all these measurements were need-based and not made as a routine. Regular recording of global solar irradiance using an MG pyranometer and a galvanometric millivolt recorder was commenced in 1955 at Delhi.

The International Geophysical Year (IGY) in 1957 provided an opportunity to Ramanathan, then a prominent member of International Union of Geophysics and Geodesy (IUGG), to propose regular measurements of radiation and ozone on a network scale in India. India Meteorological Department started four radiation stations at Pune, New Delhi, Kolkata and Chennai in 1957. To begin with, measurements of global and diffuse solar irradiances (using MG pyranometers), direct solar irradiances (using Ångström pyrhelimeter

and three broad band-pass filters) and net terrestrial radiant energy two times in the night (using Ångström pyrgeometer) at Pune and New Delhi were started; at Kolkata and Chennai, measurements of global solar irradiances and nocturnal net terrestrial radiant energy alone were made. Under the IGY programme, the network was to consist 14 stations. This could be achieved only by the year 1969 in a phased manner.

Post Independent I M D rose up to meet the demand for total indigenisation of the manufacture of meteorological instruments. The indefatigable S.P.Venkiteshwaran, with his dynamism and perseverance, started the manufacture of all types of meteorological instruments - non-recording and recording - at the departmental Workshop at Pune. The indomitable A. Mani carried this forward to its logical conclusion and achieved the task of total indigenous manufacture of meteorological instruments. The manufacture of radiation instruments is no exception. With active assistance of O. Chacko and V. Desikan, A. Mani completed the target of (IGY) projected radiation network and also started the manufacture of radiation instruments to the specified accuracy, up to par with the internationally established manufacturers. By 1976, 31 stations were operating in the Indian network. The data collected were committed to very high accuracy much beyond the WMO specifications. The years 1985 and 1986 saw a further addition of 14 stations to the radiation network density on specific requirements for those stations.

The Network:

The present strength of the Indian network of radiation stations is 45. The names with parameters measured at the network stations are given in **Table 3.1**. Their spatial distribution is also shown in **Fig. 3.1**. Since the measurements were started to cater to the specific requirements of different user organizations under different schemes, such as International Indian Ocean Expedition, Crop Weather scheme, Desert Locust Studies and the Air Pollution Scheme, the parameters measured at the stations are different. The instruments used are also, therefore, different.

Managing a network of radiation stations needs the establishment of a nodal organization with clearly defined responsibilities. The various types of sensing instruments along with their auxiliary equipment and associated items have to be well planned and acquired for eventual use at the individual stations. Such an organization has to be manned by personnel with the adequate expertise. The Central Radiation Laboratory in the Office of Deputy Director General of Meteorology (Surface Instruments), Pune, has been entrusted with the management of the Indian Radiation Network.

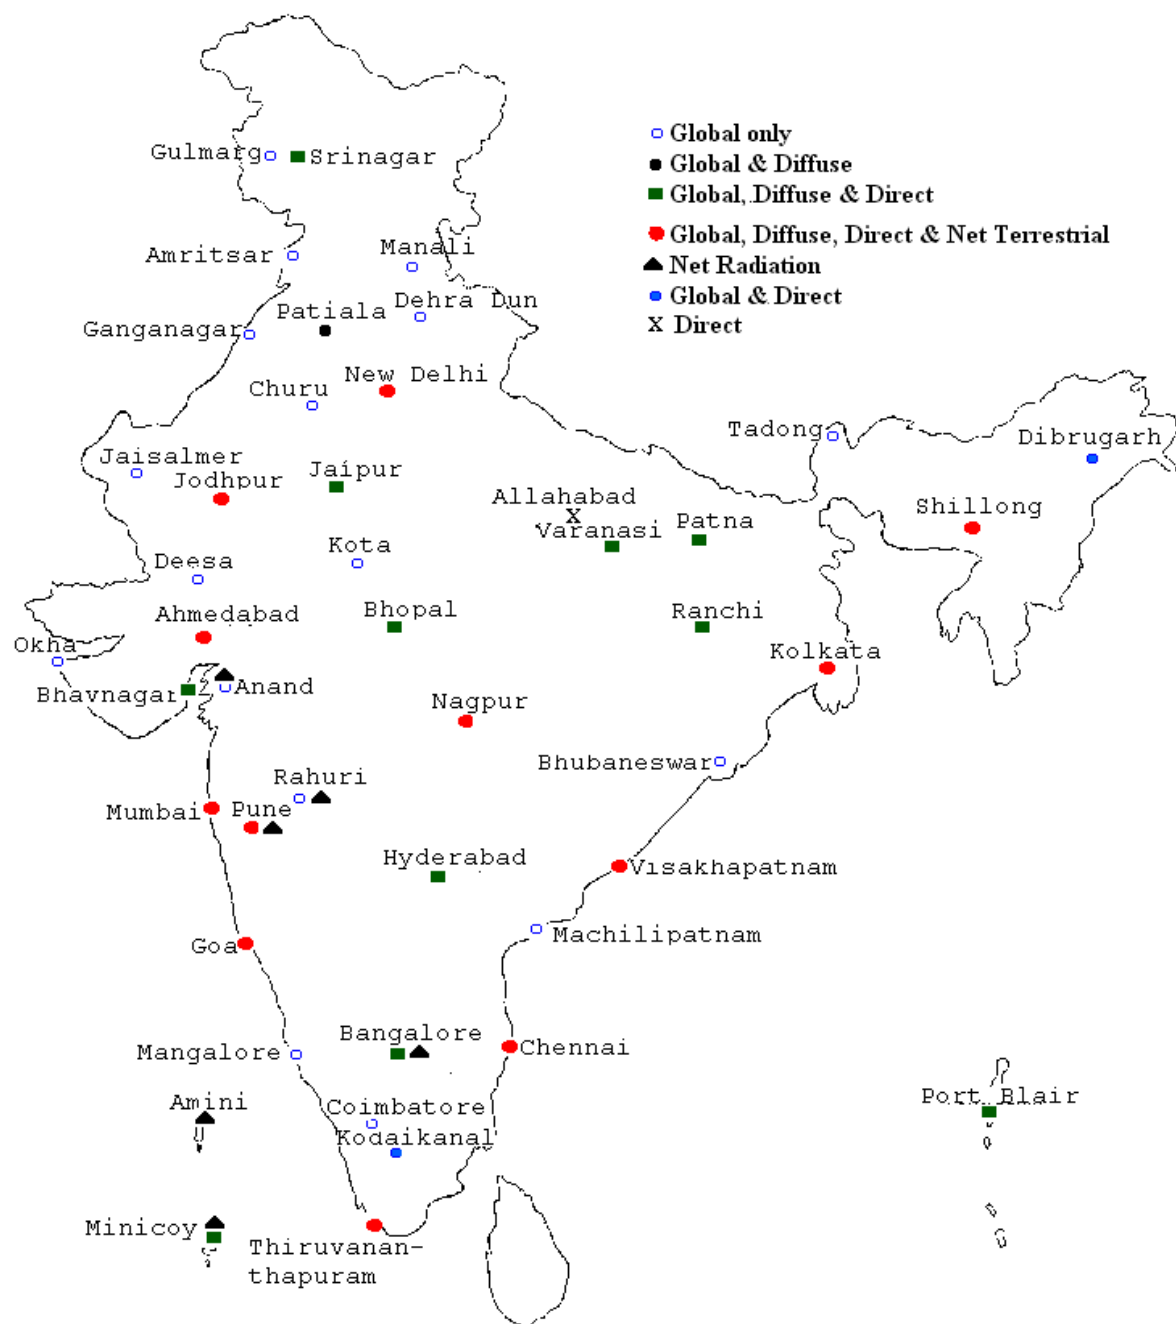

Fig. 3.1 – Radiation Network

Central Radiation Laboratory, Pune:

What started as a management laboratory for the IGY network has evolved itself into a very specialised laboratory in I M D. Since the manufacture of radiation instruments was taken up almost simultaneously, the laboratory was designated as the Central Radiation Laboratory and as the National Radiation Centre for India as well.

The laboratory carries out the following works as well:

- (i) Designing new instruments for field work.
- (ii) Manufacturing of instruments required for network use.
- (iii) Maintenance of the network by replacing defective equipment and carrying out installations where needed.
- (iv) Calibration of all instruments including standards and newly made instruments.
- (v) Maintenance of all standards - radiation as well as auxiliary equipment - required for such purposes.
- (vi) Imparting training to the field personnel.
- (vii) Maintaining a close liaison with the National Climate Centre and National Data Centre located at Pune.
- (viii) Repair of defective radiation sensors and the auxiliary equipment and their recalibration.
- (ix) Carrying out of research and development studies on the radiation instruments and carrying out scientific studies on the data generated at the field stations.

Recognising the standard of the data generated from the Indian network and of the instruments maintenance, the World Meteorological Organisation (WMO) has designated the Central Radiation Laboratory as one of the two Regional Radiation Centres for Asia, the other being located at Tokyo.

Calibration Facility

Maintaining the instruments in the network to generate a reliable database involves a close monitoring of the stability of the calibration factors of the instruments being used in the network. Even the instruments in use at the field locations need regular calibrations with reference to the standards, if possible, without disturbing the data collection process. To achieve this, the calibrations have to be done *in situ* as well. Thus a series of standards have to be maintained. The Central Radiation Laboratory has a hierarchy of standard equipment – primary, secondary, transfer, working and touring standards. **(Table 3.2)** It

maintains several working and touring standard pyranometers for routine calibration works. The Laboratory also has a series of standard lamps and blackbody radiation sources for carrying out initial calibrations in the laboratory.

The primary and secondary standards are subjected to a series of careful inter-comparisons at every opportunity for several days and a close watch is kept on their performances. These calibration results are transferred to the transfer and other standards by regular inter-comparisons in the laboratory. The working standards are used to calibrate the new instruments submitted by manufacturing entrepreneurs and various institutions. The travelling standards are taken to the field for in situ calibration works. Since field stations mostly use pyranometers, pyrhemometers and pyrgeometers, touring standards of same genre are used for field calibrations.

The field pyranometers are compared and standardised with reference to standard pyranometers and calibrated with pyrhemometers. The field pyrhemometers are standardised with reference to a touring standard pyrhemometer. Pyrgeometers are standardised by comparison with a standard pyrgeometer. The detailed procedures are given in the instruction manuals for each instrument.

The radiation data generated are with reference to the World Radiometric Reference (WRR). The calibration factors of the three primary standards of the Laboratory are always with reference to this WRR. To ensure the stability of the primary standards, one instrument regularly participates in the International Pyrhemometer Comparisons held once in five years at the World Radiation Centre (WRC) at Davos, Switzerland. The Laboratory also provides its facilities for calibration of radiation instruments of the Member Countries (of WMO) whenever a demand is made. India also participates in the Asian Regional Pyrhemometer Comparisons whenever these are arranged.

The Laboratory also maintains electrical standards for checking and standardising the auxiliary equipment like data loggers, potentiometric recorders and milliammeters. These electrical standards also undergo periodic standardisation with reference to Wheatston's Bridge and other standard equipment.

Training Facility

An important requirement for an efficient performance at a field station is the careful and proper handling of equipment and the accuracy in the data extraction. This is achieved only by imparting training to the field personnel in the basic theory of measurements and in

the practical observational activity. Central Radiation Laboratory arranges a five-week course every year at Pune for the field personnel. In addition, the visiting scientists check the individual performance at the station and impart in situ training, so that the observations are carried out properly. This training facility is available to interested scientific personnel of other scientific organizations as well.

Since the Laboratory is designated as the Regional Radiation Centre as well, personnel from other countries are also imparted training in Radiation whenever a demand is made and for periods extending up to one year depending on the specific requirement of the country.

Radiation Measurements in India

India Meteorological Department carries out the radiation measurements for the country on a network scale. There are a number of organisations in the country, who make these measurements, though not necessarily as a routine. Some of the organisations that are engaged in these activities are:

- (i) Defence Research Organisations
- (ii) Solar Energy Centre, New Delhi and associated regional test centres
- (iii) Atomic Energy Centres
- (iv) Snow and Avalanche Studies Establishment
- (v) Indian Space Research Organisation and its sister organisations
- (vi) Central Building Research Institute, Roorkee
- (vii) National Environmental Engineering Research Institute, Nagpur
- (viii) Various Indian Institutes of Technology
- (ix) Various Research Institutes under ICAR
- (x) Different Scientific Departments of Universities including Agricultural Universities and Institutions
- (xi) Different entrepreneurs engaged in manufacture of meteorological instruments

The data from them are available with the respective organisations only.

DATA MANAGEMENT

CHAPTER IV

DATA MANAGEMENT

Accuracy of Measurements:

The closeness of the agreement between the measured value and the true value of the parameter defines the accuracy of a measurement. Accuracy is a qualitative concept. When it is quantified, it is termed as uncertainty in the measured value. The uncertainty is made of several components including the systematic errors which result in the dispersion of the measured value. The accuracy of a measured value depends on the specific purpose for which it is needed. This accuracy is made of two major components (especially resolution and the stability of calibration) - the instrumental limitations and the errors caused due to other physical conditions, like the rapidity of fluctuations in the parameter, the random errors in making measurements and due to the exposure conditions. These errors may be due to inadequate observational techniques and most importantly the personal errors in making the measurements. Thus, in any measurement a deviation from the true value is always inherent and, therefore, actual performance or the achievable level of performance puts a limit to the degree of accuracy in a measured value.

Accuracy of field instruments:

The accuracy of the network data is, to a great degree, dependent on the stability of calibration factors that may show drifts over time due to regular exposure to the irradiation and improper maintenance of the instruments by different persons. The accuracy aimed and maintained in the network data is given below:

Instrument	Accuracy Specified by WMO	Accuracy Permitted by I M D
Ångström Pyrheliometer	± 0.5%	± 0.5%
Thermoelectric Pyrheliometer	± 1.0%	± 1.0%
Thermoelectric Pyranometer	± 3.0%	± 2.0%
Bimetallic Pyranograph	±5.0%	± 5.0%
Net Pyrradiometer	± 7.0%	± 5.0%
Ångström Pyrgeometer		± 1.0%

The calibrations are always carried out rigorously and carefully. Any observed deviations beyond the limits are confirmed by repeating the calibrations a number of times. If the deviations are marginally outside the limits, the calibration factors are revised to the newly determined values, taking the condition of the blackness of the sensing surface into consideration. If the deviations are significant, the field instrument is replaced by another well calibrated one. The same standard is applied for the auxiliary equipment like recorders, milliammeters and galvanometers.

Accuracy achieved in the network data:

The performance of an instrument individually and in a system under Laboratory conditions can be of very high standard due to careful and systematic maintenance care from instruments specialists. In a field condition, the harsh environment even when the atmosphere is fairly clean has its adverse effect on the performance. The exposure conditions play a major role in the quality of data. It is not uncommon to obtain a reasonably good exposure at the time of commissioning a station and later to find a substantial change in the skyline around the site over the years. Besides, the maintenance care cannot be expected to be high at the network level, due to frequent changes in the personnel depending on the overall operational requirements at each station. Many a time the persons have only *in situ* training from their colleagues and, therefore, the errors in data collection can get compounded.

Thus there can be errors in the data much beyond the instrument's accuracy. The accuracy currently being achieved in the Indian network *vis-à-vis* that specified by WMO is given below.

Parameter	Specified	Achieved
Direct irradiance-		
Spot readings	± 1.8%	± 2%
Daily totals	± 1.0%	± 2%
Global and diffuse radiant exposure	± 5.0%	± 5.0%
Total net radiant energy	± 7.0%	± 5.0%

This has become possible only through regular field calibrations, checking on the performance of the instruments by carrying out quality checks and close scrutiny of data at Pune.

Calibration of instruments:

To achieve high reliability of the data obtained, a strict watch on the various instruments, the sensors, the auxiliary recording equipment and the exposure conditions at the field has to be maintained. Besides the regular maintenance care, the performance of an instrument depends considerably on the stability of its calibration. Thus, the sensing instrument and its auxiliary equipment need regular calibration at an interval as frequent as possible. WMO guidelines stipulate down that the field radiation instruments should be calibrated at least once a year.

In India, the Central Radiation Laboratory at Pune has been designated as the National Radiation Centre and entrusted with the responsibility of maintaining the radiation network. To ensure that the network instruments are well calibrated, the Laboratory maintains a hierarchy of radiation standards as given in Chapter III (p 79).

Calibration at Pune Laboratory:

The radiation sensors made in the Instruments Division, Pune are subjected to a series of tests before their calibrations. The Laboratory checks for cosine errors and tilt effects are carried out at random in the optical set-up using lamps of known performance. They are then calibrated with the sun as the source, to arrive at the actual calibration factor for each individual instrument.

Calibration of Pyrheliometer:

The Instruments Division makes both Angstrom pyrheliometer and thermoelectric pyrheliometer. Since the Laboratory has transfer standard of both types, the calibration is carried out with the appropriate standards. A series of comparisons, each series having ten comparative values, are made and the calibration factor determined. The choice of the standard has an important role to play because of the unavoidable aureole influence and the time responses of the instruments involved. The standard deviations are also taken into account in deciding the actual calibration factor of each instrument.

Calibration of Pyranometers:

Standardisation with standard pyranometer:

After initial checks on the performance of the sensors for their suitability for network use, the pyranometer is calibrated by comparison against a standard pyranometer and a standard pyrheliometer. The standard pyranometer is mounted alongside the field pyranometer and the outputs of the pyranometers are noted at specific intervals. The ratios of the outputs of the station pyranometer to that of the standard are then grouped according to solar elevation angles like $30^\circ - 40^\circ$, $40^\circ - 50^\circ$ etc. separately for the forenoons and the afternoons. Since almost all pyranometers show large deviations in cosine response for low solar elevations and in view of the differences in the response times from one pyranometer to the other and as the variations in the irradiances are fast for low angles, the comparisons are not carried out for solar elevations lower than 20° . The ratios are tabulated for angular ranges and their means worked out. Large variations, if any, from one angular range to another indicate that the pyranometer has large cosine error or the black surface is tilted in a particular orientation. The level is then adjusted, the comparison repeated and the means are again worked out. The spirit level is then readjusted without disturbing the pyranometer levelling. The overall mean is found out and is multiplied with the calibration factor of the standard to arrive at the calibration factor of the test pyranometer.

Calibration with a pyrheliometer is done in three ways:

- (i) The test pyranometer is shaded for some period using a shading disc and the output under steady state is noted. It is then exposed to the sun and again the outputs are noted over a period of time during which a standard pyrheliometer is used to record the direct solar irradiances. The pyranometer is again shaded to record the diffuse irradiance. A mean of the output during the two shadings gives the mean output corresponding to the diffuse irradiance. The mean output corresponding to each

pyrheliometer measurements gives the corresponding output for global solar irradiance. The mean irradiance as measured by the pyrheliometer is also worked out. If V_g is the mean global irradiance in millivolts and V_d the mean diffuse irradiance in millivolts, then $V_g - V_d$ gives the direct solar irradiance in millivolts on a horizontal surface. Then the calibration factor of the pyranometer K is given by:

$$K = \frac{V_g - V_d}{S \sin \theta}$$

where, S is the mean direct solar irradiance and θ is the mean solar elevation angle during the period when the pyranometer was exposed. θ can either be measured or computed from the relation

$$\sin \theta = \sin \Phi \sin \delta + \cos \Phi \cos \delta \cos t$$

where,

Φ is the latitude of the place where the calibration is carried out

δ is the solar declination for the day, and

t is the mean hour angle of the sun at the time of measurement.

The calibration is carried out on a day with stable atmospheric conditions and several sets of calibrations are generally carried out for each pyranometer.

- (ii) The shade–unshade of the same pyranometer will result in the slight decreasing outputs even if the irradiances are steady. An additional pyranometer whose calibration factor is known is used for measuring the diffuse component by keeping it permanently under shade. The output of the test pyranometer is noted and the mean taken when the standard pyrheliometer is used to measure the direct solar irradiances. The diffuse irradiance is worked out from the mean output of the shaded pyranometer and its calibration factor. Then the calibration factor of the pyranometer is worked out from the relation

$$S \sin \theta + E_{d\downarrow} = V_g/k$$

where,

$E_{d\downarrow}$ is the diffuse irradiance,

V_g the mean output corresponding to the global irradiances and

k is the calibration factor of the test pyranometer.

- (iii) In the third method, there is no need for a standard or calibrated pyranometer. Two pyranometers which need calibration are mounted side by side and one of the two is shaded permanently for the day using a motor driven shading disc. The shadow

should just cover the pyranometer hemispherical glass domes. A pyrliometer measures the direct solar irradiance. The pyranometer outputs for the corresponding direct irradiances are noted. These measurements are made at short and convenient intervals. On the next day, the shading is done on the first pyranometer which was not shaded on the previous day. The second pyranometer which was shaded on the previous day is now kept exposed and the measurement schedule of the previous day is followed. Thus two sets of data from two pyranometers with unknown calibration factors are obtained. Two sets of equations for same timing and same optical air mass can be solved and the unknown calibration factors determined. It was found that the standard deviations among the new sets of calibrations are comparatively less even if the sky conditions are not similar on the two days.

This calibration procedure was recently developed and used by the Central Radiation Laboratory, Pune. This method is free from errors which may occur in the previous two methods.

Calibration with lamps:

Central Radiation Laboratory maintains several lamps which can be used for calibrating a pyranometer inside the Laboratory. Optical set-up for determining the deviations from cosine response is also available. In this method, the pyranometer is kept in a horizontal position and the lamp's position can be changed from 0° elevation to 90° on either side of the pyranometer. For each position, the lamp is allowed to stabilize and its output is checked for its stability with a thermopile radiometer held perpendicular to the incident beam. Only after this, the pyranometer is irradiated and the output measured. For each position of the lamp, the pyranometer output is measured when its orientation is changed to the four cardinal directions serially.

Similarly, the pyranometer is mounted on a tilting platform whose angle of inclination is adjustable. The irradiation direction is fixed and the effect of the tilt on the pyranometer is studied.

Arrangements are also available for testing a pyranometer for the temperature effect, its linearity in output and its spectral response in broad spectral bands. A temperature chamber with optical window is available for the purpose.

Sunphotometer:

The calibration is being carried out using the Langley method. On a cloudless day with reasonably stable atmospheric transmission conditions, the sunphotometer readings are taken at frequent intervals from sunrise to sunset. The readings have to be taken at very short intervals near the sunrise and sunset timings as the changes in optical air mass are very rapid. The optical air mass is computed for each measurement and necessary corrections are applied for changes due to atmospheric refraction. The logarithms of the readings are then plotted against the optical air mass. The points normally lie along a straight line which when extended backward to zero air mass gives the value of extraterrestrial reading, which is the calibration factor of the sunphotometer. A correction has, however, to be made for the sun-earth distance.

The Pune Laboratory has also a facility for checking the calibration factor for different wavelengths using spectroradiometer with gratings and photomultiplier tube. The output of the spectroradiometer in the relevant spectral band can be related directly to the reading of the sunphotometer.

Net Pyrradiometers:

Net pyrradiometers have to be calibrated for the short-wave solar radiant energy range as well as for the long wave terrestrial radiant energy range. For the solar energy range, the calibration can be made with reference to a pyrhelimeter by the shade-unshade method. Since the duration during which the pyrhelimeter is used is short, it is normally assumed that the temperature and the reflectivity of the underlying surface is constant for each calibration set.

For the terrestrial energy range, the calibration normally carried out with an artificial source can be used. The source has to be a blackbody source whose temperature is stable and its spatial radiance is uniform. Since only one surface will be exposed to the source, the temperature of the other surface has to be separately measured and radiant energy for that surface has to be worked out. The difference between the two radiances which are due to the blackbody source and the ambient air temperature then gives rise to the specific output of the net pyrradiometer. A major source of errors is the convection currents set up between the blackbody source and the surface facing it due to the inevitable temperature gradient. Similarly, the radiant energy from the blackbody source may affect the air temperature field near the net pyrradiometer. The output of the net pyrradiometer may not, therefore, become stable.

Pyrgeometer:

Ångström pyrgeometer is generally calibrated with reference to a standard Ångström pyrgeometer by comparison method. The standard and the test pyrgeometer are kept side by side at the same level and comparative measurements are taken. Several series of comparative readings are taken for durations of 10-15 minutes when the atmospheric conditions are almost steady. These are done only under cloudless sky conditions and when the wind is calm or near calm.

The standard pyrgeometer is calibrated against a known black body source. A major problem is that the black strips have to be cooled to a temperature lower than the ambient, so that these strips can be heated to raise their temperature to those of the gilded strips which are at air temperature. A block of ice insulated from external temperature effects serves as the blackbody source. Thermocouples embedded in the ice and water at room temperature enable to determine the radiant energy from the ice block. Another thermocouple is attached to the pyrgeometer to monitor the changes in its body temperature. In spite of all precautions, slight liquifaction of ice does takes place and this causes a strong temperature gradient in the field. This leads to convection currents in the enclosure.

Another method generally employed is to heat a chamber to about 50°C and keep the pyrgeometer in it. The pyrgeometer is exposed to the room temperature through a window. The air outside is cooler than the air near the pyrgeometer. Knowing the temperatures involved, it is possible to work out the calibration factor of the pyrgeometer. There is an exchange in radiant energy levels from the blackbody radiant energy emitted by the warmer pyrgeometer and that by the cooler air and the pyrgeometer measures the resultant energy caused by the relative cooling of the black strips over the temperature of the gilded warmer strips.

Field calibration in the network:

Calibrations at the Laboratory can be carried out with ease because of the facilities available. At field stations there are quite a few limitations. I M D has so far been calibrating the pyranometers without seriously affecting the daily collection of data, especially of global radiant exposure. The touring standards, viz. Ångström pyrheliometer, pyranometer and pyrgeometer, are carried to the field stations along with the necessary auxiliary equipment needed for the standards. In case of recorders, it is serviced well before checking their calibrations.

Pyrheliometer:

- (i) Ångström pyrheliometer of the field station is compared with the touring standard, using the standard milliammeter carried from the Laboratory. This milliammeter is also calibrated 4-5 times in a year on a Wheatston bridge.
- (ii) Thermopile pyrheliometer is also calibrated with reference to the Ångström pyrheliometer. Any chance of zero depression is checked by closing the pyrheliometer at regular intervals. This pyrheliometer can also be standardized with reference to a standard thermoelectric pyrheliometer.

Several comparative series are carried out and the mean calibration factor is found out. In case of significant deviations from the accepted factor in use, the series is extended, so that a large number of measurements are available to confirm the change. Should there be any change in the blackness of the receiver, the instrument is normally replaced.

Pyranometer:

The global and diffuse pyranometers are compared with reference to a standard pyranometer by installing the standard pyranometer alongside the pyranometers. The shading ring is removed during this comparison which is carried out for a minimum of three days of cloudless skies and the ratios of outputs of the pyranometers with those of the standard pyranometer are worked out and tabulated, as indicated earlier, under various solar elevation angle bandwidths. The final calibration factor is also worked out as given earlier. The global and diffuse pyranometers are, however, checked for their horizontality and readjusted, if necessary, using the levelling screws. The morning and evening ratios for each angle width will also show any large deviation in the cosine response caused by wrong levelling and due to some changes in the horizontality within the sensor area itself.

The pyranometers are also calibrated with reference to a pyrheliometer by shade-unshade method. But this is used just to check and confirm the results obtained by the intercomparison of the pyranometers with the standard pyranometer.

Pyrgeometer:

The pyrgeometer of the field station is checked for its calibration by comparison with a touring standard pyrgeometer. This is carried out in the night time when the sky is cloudless and the wind is calm. Several sets of comparative readings are taken for arriving at the calibration factor. Changes in the calibration factor are mostly due to the

deteriorations in the black colour of the blackened strips and due to the fading off of the brightness of the gilded strips.

Net Pyrradiometer:

The field net pyrradiometer is calibrated during the daytime for shortwave solar ranges by the shade-unshade method. Since the pyrhelimeter measurements for any specific set is done over a very short interval, the reflected solar irradiation and the terrestrial radiant energy field of the underlying surface can safely be assumed to be stable and isotropic.

A pyrgeometer is used to check the calibration of the net pyrradiometer for the terrestrial radiant energy wavelengths. The pyrgeometer is mounted very close to the net pyrradiometer and at the same level during this check.

Sunphotometer:

These are calibrated by the Langley method with the sun as the source. Care is taken to choose a day with a stable atmospheric condition. Should there be changes in the condition, the calibrations are repeated again to confirm the value obtained.

Auxiliary Equipment:

- (i) Milliammeter used for pyrhelimeter and pyrgeometer measurements are calibrated using a Wheatstone's bridge circuit using a standard resistance and a potentiometer (analog or digital).
- (ii) The network uses suspended mirror galvanometer with a sensitivity of 4.0×10^{-8} A for a scale division and a period of 1.8s. These are also checked during the calibration tour.
- (iii) A suspended coil galvanometric recorder is well serviced before calibration. The current sensitivity is checked carefully. The voltage sensitivity is checked with a millivolt calibrator.
- (iv) The resistances of all sensors and cables involved are also determined, so that any changes in the resistances can be noted and the cause for the changes identified. Necessary corrective action is taken thereon.

Data Compatibility:

An important requirement in data collection is that the data should be universally comparable with the data of similar kind obtained anywhere in the world. This is achieved by (i) having equipment of good and comparable accuracy, (ii) the equipment used having their calibration traceable to a reference which is accepted universally, (iii) following uniform measurement techniques and timings at all locations in the world, and (iv) subjecting the data generated in the network to a thorough scrutiny by competent persons, following the prescribed procedures.

The traceability of the data to a well defined reference standard is to be ensured by the National Radiation Centres. In India, it is carried out by the Central Radiation Laboratory at Pune. The touring and transfer standards are subjected to a series of calibration schedules every year with reference to the primary and the secondary standards. At Pune three standards of primary class are maintained. The three standards, viz. Eppley PACRAD, Eppley HF and PMO-6 radiometers, are inter-compared every year and their performances closely watched. At least one of the three participates in the International Pyrheliometer Comparisons (IPC) for the Regional Radiation standards, held once in five years at the World Radiation Centre at Physikalisch Meteorologisches Observatorium, Davos (PMOD), Switzerland. Except when the Indian Standard participated for the first time in the IPC, the calibration factor has since remained very stable within the prescribed uncertainty limit of ± 0.3 per cent.

The times of measured data are with reference to the local apparent time (also known as True Solar Time (TST)), so that the homogeneity of the data collected at different places can be achieved.

Training of field workers:

The methods of measurements being made in the network stations strictly follow the procedures laid down by WMO. The recorders used are of different types and, therefore, the data evaluation procedures vary accordingly. But these have been standardized for each type of recording. An important component in the data collection is that the person carrying out the measurement is fully competent to handle the instruments and is fully adept in carrying out the measurements. This is best achieved by imparting training to the field personnel.

The Central Radiation Laboratory has a five-week training schedule at Pune when the persons from the field stations are given brief introduction to the essentials of theory and its auxiliary equipment. Then they are subjected to intensive training in observational methods, data extraction from recorded charts and computation procedures. Individual attention is given to each participant and their daily work closely checked.

When the scientists from the Laboratory visit a station for *in situ* calibration and maintenance, performance of each person is closely checked during measurements and while extracting data. Any errors in the procedures are explained and corrective measures taken. Specific training is also imparted, if necessary, even during the tour.

Reliability of data collected:

The data generated in the network have to be of acceptable standard. Regular checks have to be made to validate the observed data. Validation of data ensures quality control, so that each value obtained has a reliability specified for such data. Quality control entails proper upkeep of measuring instruments, ensuring highest level of standards in observational techniques and practices and minimum personal errors in data extraction and tabulations. A variety of approaches exist to check the quality of measured data. These techniques vary in their degree of rigour and complexity in using them.

In the network, following checks are carried out between two calibrations at the field stations:

- (i) Central Radiation Laboratory calls for the entire data sets including recorded charts from each station and checks very closely the standard of work done by the field workers. All errors as revealed from the data sets are identified and necessary corrective steps taken.
- (ii) The stations are asked to send data to Radiation Laboratory, Pune on global, diffuse and direct irradiances when the skies are cloudless. The data can be checked using the equations:

$$E_{g\downarrow} = S \cos\theta + E_{d\downarrow}$$

where θ is the angle of incidence.

Thus a close watch on the two pyranometers and the pyrliometer is maintained.

- (iii) The radiation data received from a station are subjected to 100 per cent scrutiny in the Climatology Division in the Office of Additional Director General of Meteorology (Research), Pune and only then they are archived. Any systematic errors are pointed out to the field stations. Similarly, any doubt on the functioning of any

instrument at a station is communicated to the Radiation Laboratory for further checks and corrections, if required.

- (iv) In addition, the data are given a small margin for deviation and the outliers flagged by the computer. They are then checked and corrected before archival.
- (v) The net terrestrial radiant energy obtained using pyrgeometer is checked for consistency under identical temperature, vapour pressure, wind and sky conditions. They are also randomly checked with data derived from empirical relations established by Ångström, Brunt or Swinbank. The radiant energy values recorded by net pyrradiometer in the night are also randomly compared with the pyrgeometer values.

Archival of Data:

India Meteorological Department has brought out several publications on the radiation data sets. They include:

- (i) Monthly Radiation Bulletins
- (ii) Aerological Data of India, Part III-Radiation data
- (iii) Normals of hourly and daily global solar and diffuse solar (sky) radiation in cal/cm² (based on data up to 1968)
- (iv) Radiation Short Period Averages (1957-1975)
- (v) Radiation Atlas of India
- (vi) Monograph on "sunshine over India"
- (vii) Monograph on "Global solar and diffuse solar (sky) radiation over India"
- (viii) Solar Radiation on Inclined Surfaces
- (ix) Sunshine and computed Solar Radiation.

The solar radiation data collected and archived in the National Data Centre, Pune are available to user scientists, technologists and Institutions on payment of the necessary charges. They are available from the Office of Additional Director General of Meteorology (Research), India Meteorological Department, Pune - 411 005. The data can be obtained as hard copies and/or on floppies or CDs. They are available in the format adopted by I M D, based on the instructions prescribed by WMO.

The daily values of global and diffuse solar radiant exposure (irradiances) are also published by the World Radiation Data Centre, St. Petersburg, Russia, on behalf of WMO. The publication is titled "Solar Radiation and Radiation Balance Data" (The World Network). India regularly supplies data for selected stations for incorporation in this publication.

RADIATION CLIMATOLOGY OF INDIA

CHAPTER – V

PART A

RADIATION CLIMATOLOGY OF INDIA

Introduction:

The solar radiant energy, in its passage through the atmosphere undergoes depletion due to absorption and scattering by the various constituents of the atmosphere at different levels. While most of absorptions are due to radiatively active gases, chief of which are carbon dioxide, ozone and water vapour, the scattering takes place due to all constituents of the atmosphere including suspended particulate matter. The singlemost modifier of the radiation field is the cloud, both due to absorption and scattering processes.

Both the absorption and scattering processes take place selectively, i.e. specific gases absorb or scatter at specific wavelengths/wavelength bands. The absorption can be weak or strong and partial or total. The scattering occurs both in the forward and backward directions. The back scattering process can be termed as reflected radiant energy at the appropriate levels. Ultimately, the radiant energy that reaches the earth's surface is made of the direct beam solar irradiation, the scattered (diffuse) solar irradiation and the downward terrestriant radiant energy from the atmosphere. This heats up the earth's surface and causes evaporation of moisture in the soil and over water surfaces.

The earth's surface and the constituents of the atmosphere including clouds and particulate matter emit radiant energy in the infra-red region at their own temperatures. This energy is absorbed by different atmospheric layers at different wavelengths, resulting in higher energy level content. But these absorbing layers also emit their heat resulting in the lowering of the heat energy content. However, since the temperatures of the different layers decrease as the height increases in the tropospheric region, the downward radiant energy from the higher layers is generally lower than those emitted upward by the lower layers.

This results in a net loss of the radiant energy in the infra-red wavelengths (terrestrial radiant energy). It is in this terrestrial radiant energy regime that all living organisms including humans are immersed fully and thrive. It is also this energy field which causes the changes in the temperature of the air layer close to it and hence the density of air, leading a chain of interactions to affect the atmospheric temperature and humidity and then the atmospheric pressure and the wind field. This ultimately causes the weather patterns and the changes in them.

The amount of radiant energy from the sun over a place is not the same on each day. The varying distance between the sun and the earth contributes to a small percentage in the radiation field. Because of the tilt of the axis of rotation of the earth about itself, the length of the day and night over a place changes everyday. Also because of the tilt and the rotational movement of the earth, various parts of the earth are irradiated differently leading to differential heating of any part on the earth's surface. Superposed over this is the varying topography of the earth's terrain, the relative distances from the oceans and the latitudinal distance from the equator. Thus the amount of solar radiant energy at a place varies depending on the time of the day and the season. The amount is quite low at the time of sunrise or sunset as the radiant energy has to traverse a longer pathlength than what it will be when the sun is at its zenith position. Besides, the radiant energy is vastly affected by the different types and amounts of clouds. Naturally occurring events like volcanoes, storms and forest fires and the pollutants released into the atmosphere by the human and animal activities do reduce the amount of radiant energy reaching the earth's surface due to increased absorption and scattering effects. Thus the radiation regimes are quite likely to be different even between two adjoining regions and hence their monitoring is highly desirable and beneficial.

India has been making solar radiation measurements since 1957 on a network scale. The present network of stations has evolved over a period of about 30 years. The data pertaining to 23 network stations have been collected and are presented here after analysis. The results are briefly outlined below:

Global Solar Radiant Exposure (Global Solar Irradiation):

India, on an average, receives about 7000 MJm^{-2} of global solar radiant exposure in a year over most parts of the country. The peninsular India receives 7200 MJm^{-2} in a year over major parts while the annual highest dosage is over the Rann of Kutch which receives over 8000 MJm^{-2} in a year or an average daily of 22 MJm^{-2} . The Kashmir valley receives

about 16.5 MJm^{-2} per day, whereas it is around 15 MJm^{-2} over North-East India. This is the general picture.

The Kashmir valley receives less than 5 MJm^{-2} every day during January while the Deccan Plateau receives nearly 20 MJm^{-2} of global solar irradiation. The north Indian plains receive 15 MJm^{-2} and less during January. The major reason for this is to be attributed to the low solar elevations and the shorter duration of the day. By April the entire country is bathed with a daily irradiation of more than 20 MJm^{-2} with Saurashtra and Rajasthan receiving more than 25 MJm^{-2} . This regime continues in May too over the country outside NE India and the extreme South where the irradiation is less than 20 MJm^{-2} per day. Due to the higher incidence of clouding over the Andamans, the global irradiation during the monsoon is at a level lower by about 1 MJm^{-2} than over major parts of the country. The NW India and Kashmir, however continue to receive more than 19 MJm^{-2} per day. Andamans receive around 14 MJm^{-2} only while it is about 16 MJm^{-2} over Lakshadweep. The Tamil Nadu area and the adjoining region also continue to receive 19 MJm^{-2} or more. October once again shows a generally uniform range $15\text{-}19 \text{ MJm}^{-2}$ except the Kashmir Valley where the values drop to less than 14 MJm^{-2} from a high value of more than 18 MJm^{-2} in September. The NE monsoon with its clouding mainly affect South Andhra Pradesh and Tamil Nadu where the global irradiation is around 16 MJm^{-2} in October and it is less than 15 MJm^{-2} during November-December. The Kashmir Valley, already in the grip of winter season, receives less than 10 MJm^{-2} a day during this period.

The global irradiation field on cloudless days does show, as it should, a higher incidence of energy levels. Even the Kashmir Valley which was receiving less than 10 MJm^{-2} per day under general sky conditions receives more than 14 MJm^{-2} . Being outside the monsoon regime, it receives a maximum of 27.7 MJm^{-2} per day during June. The period March to September records global irradiation of more than 20 MJm^{-2} per day when the skies remain cloudless over Kashmir Valley. The entire country including NE and the Kashmir Valley receives more than 25 MJm^{-2} per day on any cloudless day during the year, excepting the islands in the Bay and in the Arabian Seas where the irradiation is around 24 MJm^{-2} . Even the Tamil Nadu region with its heavy clouding during November receives more than 21 MJm^{-2} on a cloudless day.

Diffuse Solar Radiant Exposure (Diffuse Solar Irradiation):

The diffuse solar irradiation is mainly due to the downward solar radiant energy scattered by the suspended particles and air molecules and the clouds. Under general sky conditions about 7 MJm^{-2} of irradiation per day is contributed by the diffuse component,

constituting about 40 per cent of the global irradiation. The coastal areas naturally record more than 8 MJm^{-2} per day, mainly due to more clouding. The winter months of December and January, a period with minimum cloudiness generally, receive around $4\text{-}5 \text{ MJm}^{-2}$ per day which is less than 30 per cent at most of the places. The monsoon season has a diffuse field of about 10 MJm^{-2} or more over most parts of the country, constituting even more than 70 per cent of global irradiation. The post monsoon sky conditions cause a steep fall in the diffuse component to an average of $6\text{-}7 \text{ MJm}^{-2}$ per day at most of the places.

The Kashmir Valley being separated by tall mountains in the west and the south from the dusty plains has a low diffuse irradiation regime. The annual value there is 5.4 MJm^{-2} only. The winter months receive less than 4 MJm^{-2} per day. After the effect of extra tropical disturbances from the West decreases by April, the diffuse values show a marginal increase to about 6 MJm^{-2} per day. The effect of summer heating is seen to be nominal as the diffuse component builds up laboriously from 6.1 MJm^{-2} in May to 7.2 MJm^{-2} in August. The autumn season causes a steep fall of 32 per cent to 4.9 MJm^{-2} per day. The diffuse irradiation field over the islands in the Bay of Bengal and the Arabian Sea is entirely different. Being warmer, the Bay area's higher cloud cover causes the diffuse irradiation to be generally higher than the Arabian Sea area except during January to April period.

The dominant factor, the clouds being absent on cloudless days, the diffuse irradiation values under cloud free skies are in the range of $5\text{-}6 \text{ MJm}^{-2}$ at many places in February. The diffuse irradiation is then mainly due to the air molecules and particulate matter in the atmosphere. Thus this is also a measure of the extent of pollution over different areas of the country. Expectedly, the hilly areas of NE have a low incidence of diffuse irradiation. Shillong has an annual value of less than 4.2 MJm^{-2} . The lowest recorded is just 2.0 MJm^{-2} in October at Shillong. It remains less than 3.0 MJm^{-2} during the period November to January. This constitutes just 14 per cent of global irradiation. Another salient feature is the high ratio of diffuse to global solar irradiation over Mumbai. It constitutes more than 40 per cent almost throughout the year. Even under cloudless sky conditions, it is on an average 35 per cent. The lowest ratio of 0.21 is recorded in February, a drier month of the year at Mumbai. The island areas of the Bay and the Arabian Sea have a 20 per cent component of diffuse irradiation in the global solar irradiation, under cloudless sky conditions.

Reflected Solar Radiant Exposure:

Reflected solar radiant exposure from the earth's surface depend on mainly two factors - on the angle of incidence of the irradiance and on the nature of surface. The nature

of surface depends on (i) the texture of soil, (ii) the type of the soil, (iii) the colour of the soil and (iv) the vegetation on the soil and its different stages of growth. Expectedly, the amount of irradiance reflected reaches maximum around the noon, even though a surface reflects maximum at high angles of incidence.

The ratio of the reflected to the global irradiance gives the reflectance of the surface. It is referred to as albedo in meteorological parlance. The albedo values are high at the times of sunrise and sunset as most of the incident irradiances are reflected at low elevation angles of the sun. As the day advances towards the noon time, the values decrease reaching a minimum at noon.

Reflected irradiation is being measured at Pune only in the Indian network of radiation stations. The reflected irradiation is minimum- 2.42 MJm^{-2} per day-during July when the soil becomes fully saturated with the monsoon rains and even a thin water layer remains stagnating on the soil. The albedo value also reaches a minimum of 0.15 during this period. Pune has black cotton clay soil whose reflectance is very low, varying from 0.12 to 0.15. It is to be noted that the hourly albedo values are minimum during June and July with noon value around 0.14 even when there is grass coverage over the soil.

Measurements made at New Delhi during earlier period indicate an albedo of 0.20. The site of measurement was of fine alluvial soil with grass growth on it. Unlike Pune, the minimum was recorded in September.

The net solar irradiation which is the difference between the reflected and the global energy values is absorbed by the earth and causes a series of changes in the energy levels inside the soil and in the atmospheric layers above it.

Direct Solar Irradiation:

The Indian radiation network makes measurements of direct solar irradiation in two forms using pyrheliometers, Ångström pyrheliometers are used at 13 stations where instantaneous measurements of spectral direct solar irradiances are made at six specific optical air masses. Ten other stations use thermopile pyrheliometers mounted on solar trackers to record continuous irradiances of direct solar radiant energy in the total solar spectrum (0.3 to $3.0 \mu\text{m}$).

(a) Direct Solar Irradiances:

The measurements are made at six optical air masses, viz. 3.0, 2.0 and 1.5, both in the forenoons and in the afternoons, whenever the sun is not covered by the clouds. All the stations excepting New Delhi and Pune use only RG₂ filters (630-2800 nm). At New Delhi and Pune two more filters OG₁ (525-2800nm) and RG₈ (710-2700nm) are also in use. Bhavnagar which was also using the three filters is no more in operation. However, its data up to 1992 have been included in these discussions.

The irradiances in the total spectrum (300-3000nm) increase sharply for an optical air mass of 2.0 FN from the earlier measurement at m=3.0 FN. The irradiances reach a maximum when measurements are made at m=1.5 FN. The decrease in the afternoons is not as sharp as it happens with the increase in the forenoons except during the pre-monsoon months, especially in May.

The soil which has been loosened by strong solar heating in the forenoons injects a large quantity of soil particles into the air. This causes sharp decrease in the irradiance levels in the afternoons. This becomes very apparent at locations in the north Indian plains from NW India to Gangetic West Bengal region. Hill station like Shillong receives an irradiance of more than 900 Wm⁻² even as a monthly average. An individual measure of 1000 Wm⁻² and more is not uncommon at such locations despite the frequent clouding at such high altitudes. When direct irradiance measurements are made using more than one filter, the data reveal the changing size distribution of suspended aerosol particles as the day advances. The effect of moist air in the variations in the size of the particles can also easily be inferred. The growth of the hygroscopic particles by coagulation and coalescence processes and by absorption processes can also be discerned. This can be easily inferred in the case of Bhavnagar where salt farming in solar ponds is in wide use. Even in Pune, the incursion of moisture during April and May due to sea breeze which occurs in the afternoons can be inferred as compared to the variations in the spectral distribution during the dry January-February months.

Though the sun reaches its highest elevations during summers, maximum direct irradiances are normally recorded during winter months because of the cloudless skies and substantial rainout of the particulates in the atmosphere during the monsoon. Thus Jodhpur and Ahmedabad record even a mean value of 700 Wm⁻² and more than 750 Wm⁻² respectively during December-January periods. The highly developed Mumbai records nearly 600 Wm⁻² mainly due to the blowing away of some of the particulate matter by the sea

breeze phenomenon. In the absence of such a scavenging mechanism, the highly urbanized Kolkata records irradiances much lower than 600 Wm^{-2} throughout the year.

(b) Hourly and Daily Direct Solar Irradiation:

Unlike with global, diffuse or reflected solar irradiation, the direct solar irradiation measurements are not affected by the cosine effect as the angle of incidence is always zero. Thus the direct solar irradiation values are generally higher than the vertical component of global and diffuse solar irradiation. When the skies are cloudless for extended periods, the direct solar irradiances can reach very high values; even values consistently higher than 800 Wm^{-2} are feasible. The recording of direct solar irradiation is achieved by having a pyrheliometer held always normal to the incident beam. This is done by mounting the pyrheliometer on a solar tracker (heliostat) driven by a synchronous motor or a stepper motor appropriately configured with a PC control or otherwise.

Srinagar, which is not affected much by the monsoon currents, records a very high value of 28.3 MJm^{-2} in April and 33.0 MJm^{-2} in May. On occasions with exceptionally good sky conditions, Srinagar receives 1000 Wm^{-2} continuously for more than an hour. There are instances when the direct irradiances exceed even 1100 Wm^{-2} as recorded at Bhopal in a March. A high daily value of 35.6 MJm^{-2} was also recorded at Bhopal during a May. In such cases the hourly values exceed 3.0 MJm^{-2} for over 7-8 hours.

However, the mean values recorded for any hour or for the day in a month do not reach that level as the irradiances vary depending on the sky conditions available. This value can be zero also, when a thick blanket of cloud obstructs the sun's rays. Such values have also been taken into account in the data tabulation. Patna with its dense population and the pollution in the air, rarely records irradiances higher than 20 MJm^{-2} in a day. In most of the locations, the high values during an hour are recorded during February-March, the months when the skies are yet to get heavily loaded with particulate matter and where the air is relatively dry at most of the places.

New Delhi and Thiruvananthapuram record direct solar irradiation on a tracker and also instantaneously using Ångström pyrheliometer. The data, even if they are co-located, need not be the same as the data recorded continuously are the mean values and not instantaneous values.

Net Terrestrial Radiant Energy in the Night:

Because of instrument limitations, the measurements are taken two times a day during the night hours only, once at 2030h IST and the other at 0530h or one hour before sunrise. Except under inversion conditions, the atmospheric layers above the earth's surface have a decreasing temperature regime with increasing altitude in the troposphere. Hence the downward radiant energy from a layer to another layer below is always less than the upward radiant energy from the lower level. Hence there is always a net outflow upward of radiant energy at each level. The actual quantity of this net (upward) terrestrial radiant energy is dependent on (i) the temperature of the emitting layer, (ii) the amount of moisture (water vapour) content immediately above, (iii) the wind field and (iv) the cloud cover above. The wind field helps in greater mixing in the atmospheric layers. The moisture has greater influence on the radiant field due to absorption in different spectral ranges. The cloud cover has by far the greatest effect on the radiation field – returning the upward energy back to the layer- thus decreasing the net field. The absence of clouds and low water vapour content in the air results in higher losses in the terrestrial radiation energy. This is easily noticeable in the data for monsoon months when the net energy is of the order of $30\text{--}40\text{ Wm}^{-2}$ throughout the country. On the contrary, January and February when the skies are generally free of clouds and the air drier, show the net energy of the order of $60\text{--}70\text{ Wm}^{-2}$. Visakhapatnam makes the measurement very close to the seas and with a strong marine environment the net energy is normally around 40 Wm^{-2} even during December-February period. The monsoon months show an average value of less than 25 Wm^{-2} during July-August to $55\text{--}58\text{ Wm}^{-2}$ in April-May period. Thiruvananthapuram, on the other hand, has a cloudy sky condition on almost every day resulting in a low but uniform field with values lying between 37 and 49 Wm^{-2} throughout the year.

Vertical Profile of Net Terrestrial Radiant Energy:

The vertical distribution of net terrestrial radiant energy is obtained using a radiometer head attached to radiosonde equipment. These measurements are made after sunset once in a fortnight at six of the stations included in the present book. The net radiant energy is worked out as the difference between the downward radiant energy measured by the top sensing surface of the radiometer head and the upward radiant energy received by the bottom facing sensor of the head. The data are tabulated for the surface level and then for standard barometric pressure levels, like 950 hPa, 900 hPa etc. The actual data sheets give values of pressure level, height in metres, air temperature, dew point temperature, relative and specific humidities, upward, downward and net radiant energy and

heating/cooling rates. The tables included in this book give only the mean net terrestrial radiant energy for each standard level for each of the six stations.

The net energy is quite low nearer the earth's surface, obviously controlled more by the higher incidence of moisture, carbon dioxide and cloud cover. The net radiant energy in the major atmospheric window (approx 8-12 μm) goes on building up from the earth's surface till it reaches the level of about 15 hPa. This trend is broken whenever a cloud intervenes. The build-up of net energy is retarded below the cloud base, it remains nearly steady inside the normal thick clouds and sharply increases above the clouds due to low temperatures of cloud tops. In the case of clouds with large vertical thickness, a gradient of increasing net energy is also observed inside the cloud layer itself. Similar cloud effects can also be seen if the balloon passes through thick layers of dust. This effect could be discerned in June over New Delhi, though it is more muted over Jodhpur.

The net energy is generally less than 100 Wm^{-2} at all stations up to 850 hPa. It reaches about 150 Wm^{-2} at 500 hPa. In the stratosphere, the values are higher than 200 Wm^{-2} . They are influenced drastically by severe thunderstorms and large clouds with strong temperature gradients. When cloudless sky conditions prevail, the increasing trend in net terrestrial energy is monotonous as is evident from the vertical distributions over Pune.

Net Total Radiant Energy:

The measurement of net total radiant energy is limited to few stations only mainly due to the limitations imposed by the inappropriate exposure conditions for such a measurement. The instrument maintenance requirements are also more rigorous. The net total radiant energy gives the balance between the net solar irradiation and the net terrestrial radiant energy. The net solar irradiation is always positive as the incoming solar irradiation is greater than the small fraction of reflected solar irradiation. Nearer the earth's surface, the net terrestrial radiant energy is invariably negative, as the earth's surface is generally warmer than the atmospheric layer above. The exception occurs only when sharp inversion in the atmospheric temperature occurs.

The controlling factors that govern the net total radiant energy over a place are (i) the cloud cover, (ii) the angle of incidence of solar radiation, (iii) hence the changes in albedo, (iv) the emittance of the surface, (v) the atmospheric temperature variations and (vi) the moisture content in the atmosphere. The undergrowth of vegetation and their conditions over a year under various weather conditions influence the albedo and emittance of the surface and also the moisture content nearer the surface.

The data included here pertain to Minicoy, Bangalore and Pune where measurements are regularly made and to Thiruvananthapuram where the measurements were discontinued since May 1992 and to New Delhi whose data pertain to periods prior to 1980. The data for New Delhi are included to give an idea on the field in the northern parts of India.

Compared to global radiant exposure fields, the net total energy field is about 25 to 50 per cent lower. The effect of marine and continental regime also plays an important role in the net radiant energy field. This ratio varies very widely but it is least during the non-rainy months, January to March and greatest during the cloudy and rainy months of the monsoon period. Both Bangalore and Pune have continental weather and black cotton soil. The ratio is more than 60 per cent during the monsoon months. New Delhi, though the data pertains to a different period, shows hardly 24 per cent of net radiant energy when compared to global solar irradiation. This may be due to the lower net solar irradiation. The controlling factors of albedo (with lower solar altitudes) and the green undergrowth of grass play a vital role in the net radiant energy field at New Delhi.

The net total value increases gradually from January to a maximum of 6-8 MJm⁻² per day during May over the Arabian Sea locations of Minicoy and Thiruvananthapuram. After May, the area is affected by the monsoon. Both places show a brief increase in September to record 8 MJm⁻² at Thiruvananthapuram and 6 MJm⁻² at Minicoy. Bangalore records nearly 12 MJm⁻² in a day during May-June and again in September. It is 10 MJm⁻² over Pune during the same months. The diurnal variations show low and negative values during the night time and the trends of global solar irradiation during the daytime. The maximum values are reached around the solar noon time. The net terrestrial radiant energy changes vary gradually from sunset (with air temperature remaining high) to sunrise. The net total value becomes zero about 20-30 minutes after sunrise and again about 20-30 minutes before sunset. Pune with heavy clouding during July-September has a net terrestrial regime of values less than 0.10 MJm⁻² throughout the night times. Similar is the case at Thiruvananthapuram. Minicoy, perhaps being an island station representing the Arabian Sea area, however has an average of 0.15 MJm⁻² during the night time almost throughout the year.

Net Terrestrial Radiant Energy at the top of the atmosphere (NTRTA):

This parameter is measured by the radiometers on board INSAT Satellite. The data are collected at IMD's Earth station at New Delhi and processed. The data were analysed and monthly mean values for the grid points covering Indian Territory have been worked out. The outgoing net terrestrial radiant energy measured by the satellite radiometer is the infra-

red radiant energy from all layers (from the earth's surface upwards) contained in the atmospheric window (8-12 μm) and the radiant energy emitted by the topmost atmospheric layer. This net radiant energy in the infra-red emitted by the earth-atmosphere system varies widely over the vast country which is home to snow capped hills, deserts, deciduous and evergreen forests and heavy rainfall areas. The values range from the low values of 150-170 Wm^{-2} to a high ones of 270-290 Wm^{-2} . Most parts of the country generally show a loss of 230-270 Wm^{-2} during major periods of the year. The exception is during the rainy summer monsoon months, June–September when the general loss in the terrestrial radiant energy is in the range 170-230 Wm^{-2} . The reduced losses are due to the extensive cloud cover and the lower earth's temperature caused by widespread rains. The high content of water vapour aid in the retention of heat which is lost by the low level atmospheric layers and the earth' surface.

The large zonal distribution of NTRTA in January over almost the whole country in the range 230-250 Wm^{-2} and 250-270 Wm^{-2} gradually expands further to cover the entire country including the adjoining Bay of Bengal and Arabian Sea during the next three months, i.e. up to April. However, NTRTA starts increasing over mid west peninsular India and adjoining Arabian Sea to a value of 290 Wm^{-2} . This higher loss ranging from 270-290 Wm^{-2} increases in extent in March to cover almost the entire peninsular India excepting Vidarbha and extreme South. This range shrinks from April due to frequent occurrence of convective clouds in the Peninsula and thus gets restricted to north Maharashtra, Gujarat and SW Rajasthan. The month May has this high loss area restricted to Gujarat and West Rajasthan. Even the range 250-270 Wm^{-2} is now over reduced areas covering entire Maharashtra, Madhya Pradesh, North Karnataka and the remaining parts of Rajasthan. The entire eastern coastal region and major parts of the Bay have losses in the range 230-250 Wm^{-2} .

The extensive clouding that results after the monsoon sets in over major parts of the country causes large reduction in NTRTA. Telengana, East Madhya Pradesh, Chattisgarh, Jharkhand, Orissa, North Andhra coastal regions and the entire North Bay lose less than 190 Wm^{-2} due to the rigorous monsoon activity in July. A drastic change occurs in August with area having the radiation losses within the range 190-210 Wm^{-2} covering most part of the country. The January pattern slowly returns as the months advance into December. On an annual scale, almost the entire country loses in the range 230-250 Wm^{-2} . Kutch and West Rajasthan and North Arabian Sea show a loss in the range 250-270 Wm^{-2} . Haryana, Punjab, foothills of Himalayas, Bengal, North-Eastern States, Head Bay and SE Bay of Bengal lose about 210-230 Wm^{-2} .

Variations in Turbidity Parameters:

In India, three types of atmospheric turbidity parameters are worked out using radiometric data. They are: (i) Linke turbidity factor **T**, (ii) Ångström turbidity coefficient **β** and (iii) aerosol optical depth **B**. The discussions given below do not compare the relative values of the different parameters nor do try to obtain any empirical relations among them.

Linke Turbidity Factor T:

The irradiance as it passes through the atmosphere gets attenuated by scattering and absorption by the air molecules and the particulate matter that remains suspended in the air. The reduction caused by air molecules is dealt in depth by Rayleigh and others and the process is termed Rayleigh scattering. The scattering caused by particulate matter including water droplets is generally treated as Mie scattering. Linke took the Rayleigh scattering as the base (as unity) and worked out the reduction as the number of Rayleigh particles needed to cause such a reduction. This ratio or the multiples of the Rayleigh scattering was termed as the Turbidity factor '**T**' and called Linke Turbidity factor **T**. Thus **T** can never be smaller than unity. In India **T** is derived for six times a day using Ångström pyrheliometer at specific optical air masses at some stations and also as hourly means using the hourly totals of direct solar irradiance using thermopile pyrheliometer mounted on solar trackers.

Turbidity Factor at specific air masses:

The turbidity factor values are found generally to range between 4.0 and 6.0 at most of the places. The values are least during the winter months and increases gradually during the pre-monsoon months when convective currents in the air lift up the soil and dust particles to higher levels. The factors decrease considerably after the rainy season is over. It is noticed that the **T** values increase from morning onwards till optical air mass reaches 2.0 and then show a small decrease. Kolkata stands more polluted with **T** values generally between 6.0 and 8.0 possibly due to the local industrial pollution and higher incidence of moisture there. Only Goa, located under the marine influence with least industrial installation, show **T** values less than 5.0 and in many cases less than 4.0. It is also seen that the stations north of 20°N, .i.e. mostly in North India, record higher values of **T** probably because of the locations in the subtropics. There are instances when Shillong has registered **T** even less than 3.0. Shillong is, however, a high altitude station.

Hourly values of Turbidity Factor 'T':

The hourly means 'T' are calculated based on the hourly values of direct solar irradiation. The hourly value is divided by 60 and the optical air mass value at the middle of the hour is used to obtain the Linke turbidity factor. Since the hourly values may not be uniformly cloud free throughout each hour, the value of direct solar irradiance that is used may not be the highest and hence T values are uniformly quite high. Given the variability in the atmospheric transparency affected seriously by haze, cirrus haze, tenuous cirrus and other forms of clouds, the hourly values of T at best can be a useful tool to assess the hourly atmospheric conditions at place during a given period.

A striking feature noted is the gradual increase in T as the day advances into the afternoon. As the optical air mass starts increasing rapidly, T values show a decreasing trend at almost all stations and throughout the year. A natural feature is the very high values of T during June-September period when the skies are not completely cloud free even within one hour. Srinagar, however, being out of active monsoon region, has T values less than 10.0 even in June and then again during September-November period after the clouding due to weak monsoon circulation effect, ceases by the end of August. However, the extra tropical low pressure disturbances moving across eastward causes sharp increases in T during the period December to April. Almost all other stations with the exception of Bangalore and Thiruvananthapuram exhibit sharp decrease after the south-west monsoon current weakens or withdraws from October onwards. The two extreme southern stations continue to be disturbed by the winter NE monsoon and hence exhibit large T values even in December.

Ångström Turbidity Coefficient β :

Turbidity coefficient computations are done using the attenuation caused in the broad spectral range 300nm to 630nm. The reduction for Rayleigh scattering is included in this. This value being a ratio with respect to the extraterrestrial value in the specified range, is always a fraction and generally smaller than 0.150. The stations considered are restricted to ones where Ångström pyrheliometer is used and hence the data pertain to the observations made at specific optical air masses.

As in the case of T, β also has values smaller for $m=3.0$ in the afternoon as compared to those for $m=2.0$ AN. Here again the forenoon β values increase as the solar altitude increases. The convection currents set up by the solar heating of the soil raises the soil and dust particles by noon. This results in the higher β values in the afternoons. The

industrially advanced areas of New Delhi, Kolkata and to some extent Ahmedabad have β values consistently greater than 0.100. Surprisingly, Nagpur also has consistently high β values. Perhaps in all these places, the scavenging mechanism other than the gravitational precipitation is either absent or weak. Mumbai with its marine wind field perhaps accounts for a slightly lower β ; the aerosols are likely to be blown off regularly by the winds. Similarly, the β values over Visakhapatnam are quite low, again perhaps because of the very close proximity of the sea. Though almost all stations have some values for the monsoon period, viz. June-September, the data may not be representative because of the scanty measurements and the possibility of very high cirrus haze at most of the places during the very few measurements that have been made.

Aerosol Optical Depth B (AOD):

AOD is computed based on the radiometric measurements made using a narrow bandwidth filter with the central wavelength at 500 nm, the wavelength very close to the wavelength at which maximum solar irradiance is received and at which the scattering is mostly due to dust particles only. The instrument, the sunphotometer, is used to make instantaneous measurements at specific times, six times a day under cloud free sun conditions. Since the optical path length is not conserved, the study of the data has also to take the appropriate optical air mass values into consideration while drawing inferences.

Like T and β , AOD also shows decrease in late afternoons and increases from morning to noon. The AOD measurements are being made at stations which act as a background stations for monitoring the atmospheric pollution. As in the case of T and β , AOD also gradually increases at all places as the season advances from winter to the hot weather pre-monsoon period. The normal trend of lower turbidity during the post monsoon period as compared to the turbidity in the pre-monsoon period is also noticeable here as well. A striking feature is the high values of AOD over Minicoy vis-à-vis the values over Port Blair by an average of 36 per cent. During the dry month February, Port Blair is lower by 69 per cent with a value of 0.115 at 1430 h of observation. Jodhpur remains fairly low with a value lower than 0.100 during the winter months. Srinagar with the extratropical disturbances during winter shows a sharp decrease by April - nearly 19 per cent from its March value of 0.145. It remains small up to July when the clouding builds up due to peak summer and weak moisture incursion. AOD values over Nagpur confirm that the place has higher particulate matter in the air than that for a background station with values generally more than 0.259 except during the winter when the values are, however, still higher than 0.200. Visakhapatnam has a somewhat steady AOD values around 0.150 almost throughout the year.

Atmospheric Transmission Coefficient ' q ' :

The atmospheric transmission coefficient gives the transmissivity of the atmosphere to the incident solar irradiation. This is derived from the measurements of direct solar irradiances using Ångström pyrheliometer at specific optical air masses whenever the sun's disc is free of clouds. When coloured band pass filters are used, the spectral transmissivity can also be worked out in the appropriate spectral bandwidths. This is done as a ratio with reference to the extraterrestrial solar irradiance in the relevant spectral bands. The parameter gives the transmission factor which is due to the attenuation caused by the scattering and absorption interactions as the irradiation passes through the atmosphere.

Only three stations, viz. New Delhi, Bhavnagar and Pune, have data for various spectral regions. The q values have, therefore, been computed for the different spectral regions for these locations. The extraterrestrial irradiances for the corresponding spectral bands were taken from the Solar Radiation Manual published by WMO. The details of spectral regions involved are given in Part B of this chapter. In contrast to the turbidity parameters, q values were higher for larger air masses, i.e. in the morning hours and in the evening hours, when the solar radiation is from lower solar elevation angles. The turbidity parameters were lower at these hours, so that more irradiances can reach the surface. This would then mean that the transmissivity of the atmosphere is more. Thus q for larger air masses is higher than the forenoon hours. However they are marginally lower in the afternoons. All stations have a transmission value lying in the range 60-70 per cent for the entire solar spectrum. As in the case of turbidity coefficient β , q values also decrease as the hot weather pre-monsoon season advances, the lowest being in June when the soil gets heated and the particulate matter easily lifted up by the winds. This is true even for the monsoon areas, as the soil continues to get heated till the monsoon rains cool the surface. Over Delhi q drops to as low a value of 50 per cent in this period due to the load of loosened soil particles. As the rains start only in July, Delhi's low q extends even into July. Similar is the case with Jodhpur which is in an arid region. Although other sites also display the similar decreasing trend, the lower limit hovers normally between 55 and 60 per cent.

Shillong with its reduced pollutants, however, has q generally over 70 per cent almost throughout the year. Similarly, the coastal stations on the West Coasts viz. Mumbai, Goa and Thiruvananthapuram, have a higher transmissivity (greater than 60 per cent) even during May-September period possibly because of the strong westerly monsoon winds and their efficient scavenging effect. Mumbai, though industrially advanced and highly

urbanized, has better transmissivity condition when compared to the inland locations like Ahmedabad, Nagpur or Kolkata.

The transmission in the infra-red region is generally higher than that in the visible. It is naturally so as the scattering effect is maximum in the shorter wavelengths with minimum absorption. For effective decrease in the infra-red where scattering is not significantly high, the absorption has to increase. Given a near steady CO₂ concentration at a location, the only controlling factor will be moisture and prevalence of hygroscopic particulate matter.

PART B

The Data

This part deals with the mean values of different parameters collected over the 15-year period 1986-2000. The data presented here are mostly in the form of tables (**Appendix II**) and some of them are presented in the form of diagrams (**Appendix I**) as well. The data in tabular form are in two formats.

- (i) Tables 1-20 contain data as mean monthly values for the whole country.
- (ii) The remaining tables give data on radiation and meteorological parameters for each station. The numbering of the tables in this format begins with three lettered abbreviation for each station (e.g. SRN-1 gives hourly global solar radiant exposure at Srinagar).

The abbreviation for each station is given in table 5.1. The 23 stations are arranged according to increasing latitude starting from Minicoy. Since the parameters measured are not uniform at all stations, the total number of tables is different for each station but the tables are arranged in the same sequential order.

The normal order in which the data presented is:

- (i) Global and diffuse solar radiant exposure data for all sky conditions, for cloudless sky conditions, the frequency distribution and the ratio of diffuse to global solar radiant exposures.
- (ii) Mean hourly solar elevation and solar azimuth for each station.
- (iii) Direct solar irradiances S at specific air masses and hourly irradiation – Different turbidity parameters and atmospheric transmissivity derived there from.

(a) The different spectral ranges included are:

Irradiance	Transmittance	Spectral Range
S_t	q_t	300 nm – 3000 nm
S_1	q_1	525 nm – 2800 nm
S_2	q_2	630 nm – 2800 nm
$S_{8,}$	q_8	710 nm – 2700 nm
S_{t1}	q_{t1}	300 nm – 525 nm
S_{t2}	q_{t2}	300 nm – 630 nm
S_{t8}	q_{t8}	300 nm – 710 nm
S_{12}	q_{12}	525 nm – 630 nm
S_{28}	q_{28}	630 nm – 710 nm

Only three stations, viz. Pune, Bhavnagar and New Delhi, had all the three coloured glass band pass filters OG_1 , RG_2 and RG_8 to give the spectral data for all the nine spectral ranges. The remaining ten stations where Ångström pyrheliometer measurements are made have only RG_2 filter. Hence the data presented here are restricted to S_t , S_2 , and S_{t2} and q_1 , q_2 and q_{t2} .

(b) Hourly direct solar irradiation and Linke turbidity factor **T**: The values given are the monthly hourly total irradiation. The Linke turbidity factor is found by converting this hourly value into Wm^{-2} and then determining **T**. Thus the value of irradiance in Wm^{-2} need not be the actual value at the middle of the hour. The values given show the trend in diurnal variations in **T** on a monthly basis.

(iv) *Net Total Radiant Energy:*

The data pertain to three stations- Minicoy, Bangalore and Pune- that are currently in operation. Thiruvananthapuram data cover the period 1986 to May 1992 when the measurements were discontinued due to technical reasons. The data for New Delhi are presented here, though the data pertains to the period prior to 1978.

(v) *Reflected Solar Radiant Exposure and Albedo:*

This is restricted to the measurements being made only at Pune. The albedo values are derived as the ratio of reflected to global solar radiant exposures.

(vi) *Vertical Profile of Net Terrestrial Radiant Energy in the Night:*

Only six among the 23 stations under consideration take radiometersonde observations once in a fortnight, after sunset hours. The data presented here are in Wm^{-2} and the mean values for the pressure levels at the standard 50 hPa intervals up to 200 hPa, then at 25 hPa up to 25 hPa and 5 hPa beyond that. The values are negative in the real sense as the surface/layers involved generally lose energy to the higher layer except at tropopause and stratospheric layers.

(vii) *Net Terrestrial Radiant Energy in the Night:*

The data are generated by actual measurements using Ångström pyrgeometer during the dark hours once at 2030h IST and again at 0530h or at an hour before sunrise. The instrument directly measures the net energy E_i^* . The upward emitted radiation is obtained from the relationship $E_{i\uparrow} = \sigma T^4$ at the air temperature T K. The difference between $E_{i\uparrow}$ and E_i^* gives the downward terrestrial radiant energy $E_{i\downarrow}$. The tabulations given incorporates the values of $E_{i\uparrow}$, $E_{i\downarrow}$ and E_i^* at 2030 h and at 0530 h under general sky conditions and under cloudfree conditions as well. There are 12 stations in these tabulations.

(viii) *Tilt Factors for Global Radiant Exposure:*

These tilt factors are used to obtain the global solar radiant exposure on a tilted surface of known azimuthal orientation. The values on the tilted surfaces are worked out by multiplying the global solar radiant exposure values at any given time by the appropriate tilt factors. These factors were calculated based on the actually measured values of global and diffuse solar radiant exposure received on horizontal surfaces and using appropriate mathematical relations given in Chapter VII. The computations carried out for surfaces facing South for five tilt angles, a tilt corresponding to (i) the latitude ϕ of the place, (ii) $\phi + 15^\circ$, (iii) $\phi - 15^\circ$ (iv) $\phi = 22.5^\circ$ and (v) $\phi = 90^\circ$. The factors are different for the same tilt angle, if the azimuthal orientation is other than South. Corrections for such deviations from South are given in the lower tabulations. These corrections are applied to the tilt factors for the surface facing South by multiplying the correction factors with the given tilt factors. The azimuth correction factors can at times be less than unity for some hours of the day.

(iv) *Meteorological parameters:*

Hourly values of pressure, temperature, relative humidity, wind speed, rainfall and duration of sunshine are also included in the tabulations. All the tables are for 24 hours' duration in IST except for the sunshine for which it is in LAT from sunrise to sunset. The data on cloud cover are estimated values for each synoptic hour. They are for low (L), medium (M), high (H) and total (T) cloud covers.

The measurement of pressure is done using a microbarograph. Air temperature and relative humidity are obtained from bimetallic thermograph and hair hygograph kept in a double size thermometer shelter screens at a height of about 1.2 m above the ground level. Wind measurements are made using either a Dine's pressure tube anemometer or an electrical anemograph installed at a height of 10 m or more above the ground. Duration of sunshine is recorded using a Campbell Stoke's sunshine recorder installed mostly alongside the pyranometers. However, all the 23 stations included here are not uniformly equipped with the autographic instruments. It is also quite possible that any of the recording instruments might have become defective and no useful records obtained for extended periods. Then the hourly data available are too scanty to work out the long term means.

In such cases the hourly tabulations are replaced by the tabulated data obtained from the synoptic observations. A synoptic observational schedule involves instantaneous measurements manually. The parameters covered are:

(i) wind speed, (ii) wind direction, (iii) air temperature, (iv) wet bulb temperature, (v) maximum temperature, (vi) minimum temperature, (vii) rainfall, (viii) visibility, (ix) estimation of cloud cover and type (x) prevailing weather phenomenon and (xi) atmospheric pressure.

The synoptic measurements are made at selected times in a day. The international practice is to take measurements eight times a day at 00, 03, 06, 09, 12, 15, 18 and 21 hours UT (universal time or GMT). The corresponding Indian timings are 0230, 0530, 0830, 1130, 1430, 1730, 2030 and 2330 h IST. Most of the stations included in this work make eight observations a day. However, there are some stations where the measurement schedule is restricted to fewer observational hours. The data tabulated here in the absence of hourly tabulations may not thus be uniform for eight hours. The cloud data given are for synoptic hours only.

Units of data used:

1)	Global solar radiant exposure *	MJm^{-2}
2)	Diffuse solar radiant exposure *	MJm^{-2}
3)	Reflected solar radiant exposure *	MJm^{-2}
4)	Frequency distribution	percentage
5)	Ratio of diffuse to global radiant exposure	-
6)	Albedo of a surface (ratio)	-
7)	Direct solar irradiation *	MJm^{-2}
8)	Direct solar irradiance (total and spectral) *	Wm^{-2}
9)	Net total radiant energy *	MJm^{-2}
10)	Net terrestrial radiant energy (on earth & extra terrestrial)	Wm^{-2}
11)	Vertical profile of net terrestrial radiant energy	Wm^{-2}
12)	Duration of sunshine hours	h
13)	Atmospheric pressure	hPa
14)	Air temperature	$^{\circ}\text{C}$
15)	Relative humidity	percentage
16)	Wind speed	Kmh^{-1}
17)	Rainfall	mm
18)	Turbidity parameters	-
19)	Transmission coefficients	percentage
20)	Cloud cover	Octa

The units used are in SI units only. The radiation data marked '*' are traceable to the World Radiometric Reference (WRR) scale through a hierarchy of standard instruments.

C h a p t e r - VI

REPRESENTATIVE METEOROLOGICAL YEAR

CHAPTER – VI

REPRESENTATIVE METEOROLOGICAL YEAR

Introduction:

The weather over a place changes continuously even within a day. Though the weather can be broadly classified into selected patterns, variations do occur within a class itself. It changes over a period. It does not recur on the same date of the same month as compared to a previous or even over successive years, even if the other environmental conditions remain nearly the same. The climatology which gives the average weather condition at a place on a specified time of a year does not necessarily mean that the conditions given by it will be reproduced in a year or even in several successive years. Thus variations within a climatological condition of a place cannot be ruled out. The climate at a place is controlled by several climatic elements which may behave in different ways in a given environmental condition at the same place.

But when a device is to be designed to work in all environmental conditions, the designer needs the meteorological data on specific meteorological parameters as per requirement. A generalised climatic data with some variations may not be sufficient for the purpose. In this case the data needed should be more realistic, i.e. should be typical one for the place where the design has to perform. A designer of solar system has to develop it to ensure maximum efficiency and to evaluate its performance *vis-à-vis* different system designs. The computer codes used by designers to simulate and predict the energy output of the actual system need meteorological inputs which may closely match with the actual conditions. The predicted performance of the device will depend on the meteorological inputs. A system designed on particular inputs may function very poorly using a different input.

Thus the need for the value of a standard database representative of a given area is apparent. It should be, in a sense, representative of the long-term database and it should cover a period of one year. Such a data is termed representative year or typical meteorological year (TMY).

Some of the requirements needed to arrive at the representative data are:

- (i) The cumulative frequency distribution of the meteorological parameter e.g. global solar radiant exposure should be close to the long-term cumulative distribution.
- (ii) The sequence of occurrence of the specific measure should be representative of the sequence of occurrence at the site.
- (iii) The interrelationships among the parameters that are being used should be comparable with those that occur in nature.

There have been several attempts to arrive at the typical meteorological year. The one that has been carried out in this handbook is based on the method developed by the Sandia National Laboratories, USA. The TMY data is for use in computer simulations of solar energy conversion systems and building systems. A TMY permits performance calibration of the system types and configurations. A TMY is not necessarily a good indicator of conditions in the future. It only represents conditions judged to be typical over a long period of time, say 30 years. Since they are typical values, they are not suitable for designing systems, meant to be used for the worst conditions occurring at a place. The Sandia method is basically an empirical approach. A typical month for each month in a year is worked out from long-term database. The values of these individual typical meteorological months (TMM) are concatenated later to form a year. Thus each month chosen can be from unconnected years. Sandia method uses nine parameters to select a month. The parameters used are temperatures, dew point temperatures, wind velocity and the mean global solar irradiances. Monthly statistics are worked out for each parameter (index). Month/year combinations which have close agreement with the long-term statistics are grouped for further consideration. Final selection of the TMM is based on persistence of weather patterns.

The Method:

The method uses ten indices in this publication. They are monthly means of:

- (i) Global solar irradiance (radiant exposure)
- (ii) Diffuse solar irradiance (radiant exposure)

- (iii) Maximum air temperature
- (iv) Minimum air temperature
- (v) Mean air temperature
- (vi) Maximum dew point temperature
- (i) Minimum dew point temperature
- (ii) Mean dew point temperature
- (iii) Maximum wind speed
- (iv) Mean wind speed

The processing involves determination of mean for each month for each year for each station along with the standard deviation and median. The long-term mean for each index for each month is also worked out. This would mean that there would be 31 values of each index for say January of each year. The long-term values based on 15 years' data will have 465 values to be considered.

Selection of candidate months:

This is done in two stages. The first is to select five years which are close to the long-term values. The next stage is to select the TMM from these five years.

(i) Selection of five candidate years:

For each month, the cumulative distribution function (CDF) is determined. The CDF gives the proportion of values which are less than or equal to a specified value of an index. The CDF for each year for the specific month and for the specific index is compared with the long-term CDF for that specific month and for the same index. The comparison for each index is carried out for five CDFs that are closest to the long-term CDF by using the Finkelstein-Schafer (FS) statistics. The FS statistics is given by:

$$FS = \frac{1}{n} \sum_{i=1}^n \delta_i$$

where,

n = number of daily readings in a month (31 in say January)

and δ_i = the absolute difference between the long-term CDF and the candidate month CDF at x_i

FS value will be the smallest if the two CDFs are closest.

The role of each parameter is different for different applications. This would mean that certain weightage has to be accorded to each parameter. A month that had the least value of FS for each index would be the best choice. In practice, however, every index does not provide such closest agreement to the long-term value. By weighting the FS statistics, it is possible to take into account the relative importance and sensitivity of the indices.

The actual weighting scheme used here is as follows:

The maxima and minima of air temperature and dew point temperature were accorded minimum non-zero weight (of 1). Mean wind velocity, mean air temperature and mean dew point temperature were given a weight of 2 each. Maximum wind velocity was given a weight of zero as it was considered not to be of importance as it is transient in occurrence. The global and diffuse irradiation values were given in a weightage of 7 and 6 respectively.

The values actually used are tabulated below:

Global solar irradiance	7/23
Diffuse solar irradiant	6/23
Mean air temperature	2/23
Maximum air temperature	1/23
Minimum air temperature	1/23
Mean dew point temperature	2/23
Maximum dew point temperature	1/23
Minimum dew point temperature	1/23
Mean wind speed	2/23

(ii) **Ranking of TMM**

The five months that are close to the long-term mean and median are ranked.

(iii) **Persistence:**

The persistence of global and diffuse solar irradiance is evaluated by determining the frequency and run length above and below fixed long-term percentile. For global irradiation the frequency and run length below the 33rd percentile (consecutive low radiation days) were used. For diffuse irradiation, above 67th and below 33rd percentile were considered.

(iv) Representative month:

The final selection of the typical month was made from the months given under (iii) the month and the year with small weighted sum (WS) values and small deviations is selected. The mean values are checked by means of its closeness to the median. The standard deviations for the major parameters i.e. global and diffuse irradiation and temperature, tell all about the persistency of the conditions. This is repeated for each month of the 12 months of a year and for each station.

(v) Representative data year:

The 12 selected months were then concatenated to make a complete year. The representative year data for each station consists of 12 months of actual meteorological data which are selected from long-term database for a specific station. A representative meteorological year may, therefore, contain data of a month of a particular month from a specific year and the next month data may be from yet another year. The data for each month from different specific year for a station are then concatenated to form a representative year.

Table 6.1 gives the years of data for different months used for each station. The data are for hourly values for each parameter, if available. In the case of absence of autographic instruments or non-availability of data, the available synoptic data for selected parameters are given. In case of month interface, the data for six hours on either side of the month interface are smoothened to ensure an apparent continuity. The data set does not include any synthetic generation of hourly data from the three hourly synoptic data by Fourier expansion or any other method. The data are not in print form and they are available only on a CD as a soft copy.

The representative data sets are given for 22 stations only. Srinagar has not been included because the data available are scanty for this purpose. In the case of Bhavnagar, the period considered is from 1986 to 1992 only as the station discontinued the data collection from February, 1993.

CONNECTED ALGORITHMS

CHAPTER VII

CONNECTED ALGORITHMS

Among the various factors that contribute to the variations in the quantity of solar radiant energy that reaches the earth's atmosphere, two factors are of astronomical nature. They are the sun-earth distance and the apparent declination of the sun. The solar constant varies significantly throughout the year depending on the actual sun-earth distance R . The solar constant on a given day can be expressed as

$$S = \bar{S}_o \left(\frac{Ro}{R} \right)^2 \quad \text{.....7.1}$$

where, \bar{S}_o is the mean value of solar constant = 1367 Wm^{-2}

$$\left(\frac{Ro}{R} \right)^2 \text{ can be determined (as given by WMO Radiation Manual, Ref.63)}$$

$$\begin{aligned} \text{from } \left(\frac{Ro}{R} \right)^2 = & 1.000110 + 0.034221 \cos\theta_0 + 0.001280 \sin\theta_0 \\ & + 0.000719 \cos 2\theta_0 + 0.000077 \sin 2\theta_0 \quad \text{.....7.2} \end{aligned}$$

where, $\theta_0 = \frac{2\pi d}{365}$, 'd' is Julian day counted from 1 January. R/R_o is also known as the radius vector. The mean value of the correction factor for each day of the year is given in Table 7.1.

7.2 Declination of the sun:

The declination of the sun is the angle given when the line of right ascension cuts the hour circle and is generally denoted by δ . The declination δ in radians can be derived from the approximation (from Radiation Manual)

$$\delta = 0.006918 - 0.399912 \cos\theta_0 + 0.010257 \sin\theta_0 - 0.006758 \cos 2\theta_0 + 0.000907 \sin 2\theta_0 \quad \dots\dots 7.3$$

However, a mean value, in degrees, of the declination for each day of the year is given in Table 7.2

7.3 Equation of time:

The civil time followed is based on the mean solar time. A mean sun is postulated to be one which moves along the celestial equator with constant speed. The time interval between two successive upper transits of the mean sun across a meridian gives the mean solar day. However, in the actual case, the speed varies and the time interval between two successive upper transits gives the actual solar day. The difference between the two is termed as the equation of time (E_q). The time based on the actual solar day is called the Local Apparent Time (LAT) or The True Solar Time (TST).

Thus, $LAT = LMT + E_q$ where LMT is the local mean time, the civil time corresponding to the longitude (meridian) of the place. WMO (Ref.64) gives an approximation relation.

$$E_q = 0.0172 + 0.4281 \cos\theta_0 - 7.3515 \sin\theta_0 - 3.3495 \cos 2\theta_0 - 9.3619 \sin 2\theta_0 \quad \dots\dots 7.4$$

where, $\theta_0 = \frac{2\pi d}{365}$ in radians or $360d/365$ in degrees, 'd' being the Julian day as stated earlier.

The mean value of equation of time for each day of the year is given in Table 7.3

7.4 Solar elevation and azimuth:

Many of the problems while using radiant energy for meteorological applications need the values of the actual location of the sun in the sky at a given place and time of a particular day. The solar elevation angle 'h' is given by

$$\sin h = \sin \phi \sin \delta + \cos \phi \cos \delta \cos t \quad \text{.....7.5}$$

where,

ϕ = latitude of the place

δ = declination of the sun for the particular day

t = solar hour angle, in degrees, calculated with reference to solar noon time ($t=0$ at solar noon)

The azimuthal position A is given by

$$\sin A = \cos \delta \sin t / (\sin h) \quad \text{.....7.6}$$

where, the azimuth angle (A) is measured from North as 0° and clockwise through East.

7.5 Beer's Law:

The radiant energy as it passes through the atmosphere is attenuated due to absorption and scattering processes as a result of the interaction between the radiant energy and the constituents of the atmosphere. The attenuation depends on the path-length through which the radiant energy has to penetrate and on the different constituents of the atmosphere it has to encounter. When the incident energy is at normal incidence, the irradiance received at the earth's surface can be expressed by Beer's law as

$$S_\lambda = S_{0\lambda} e^{-a_\lambda m} \quad \text{.....7.7}$$

where,

S_λ = spectral irradiance in the wavelength λ at the earth's surface.

$S_{0\lambda}$ = corresponding extra terrestrial irradiance

a_λ = attenuation factor at the wavelength λ due to absorption or scattering and

m = the optical path length or optical air mass.

The Beer's law is also called Bouguer-Lambert Law. In pyrheliometry (including sunphotometry) this law is used to derive the turbidity parameters.

7.6 Optical Air Mass:

The optical path length through which the irradiation traverses is called the absolute optical air mass. The relative air mass m_h is worked out as the ratio of the air mass along the slant path of the irradiation to the air mass in the vertical direction.

$$m = 1/\sin h$$

where, h is the solar elevation angle given by equation (7.5).

In the real atmosphere, refraction interferes with the incident rays and a correction has to be applied incorporating corrections for changes in temperature and pressure. When the atmospheric pressure is different from 1013 hPa, then the optical air mass 'm' is given by:

$$m = m_h \frac{P}{1013} \approx \frac{P}{1000} \quad \dots 7.8$$

When the sphericity of the atmosphere and the refraction effects are taken into account, the relative air mass can be expressed by (CIMO Guide)

$$m_h = \frac{1}{\sin h + 0.15(h + 3.885)^{-1.253}} \quad \dots 7.9$$

where, h is expressed in degrees.

7.7 Turbidity Parameters:

Beer's law as expressed by equation 7.7

$$S_\lambda = S_{0\lambda} \cdot e^{-a_\lambda \cdot m}$$

gives the irradiance S_λ at normal incidence after the irradiation passes through the medium. After the absorption effects in the ionosphere, mesosphere and stratosphere and the absorption of major part of infrared wavelengths by water vapour in the troposphere, the irradiance is restricted to solar radiant energy contained in the wavelength band 290 nm to 3000 nm. Even within this band, there are absorption bands due to ozone, water vapour, oxides of sulphur and nitrogen. Besides, the scattering due to air molecules and aerosol

particles also causes considerable attenuation. The most important attenuating factor is the different types of clouds.

The attenuating term a_λ in the Beer's law can, therefore, be resolved under cloud free conditions into different components such as:

$$a_\lambda = a_R(\lambda) + a_D(\lambda) + a_W(\lambda) \quad \dots 7.10$$

where, $a_R(\lambda)$ = extinction due to Rayleigh scattering by air molecules and particles of size smaller than the wavelength of irradiance

$a_D(\lambda)$ = extinction due to aerosol particles in the atmosphere

$a_W(\lambda)$ = extinction due to selective absorption by water vapour in the atmosphere.

By restricting the measurements to wavelengths in the visible spectrum ($\lambda < 700$ nm), the effect of highly variable water vapour can be circumvented. The symbol τ_λ is also used in place of a_λ .

The air molecules of the atmosphere scatter the radiant energy in the direct beam. This scattering is inversely proportional to the fourth power of the wavelength. The scattered energy becomes insignificant for longer wavelengths especially for wavelengths longer than 800 nm. Thus shorter wavelengths of irradiation get scattered more strongly than the longer wavelengths. Based on the recommendation of WMO made during IGY, IMD has been using a relation for $a_R(\lambda)$ as

$$a_R(\lambda) = \frac{P}{P_0} \cdot 0.00897 \lambda^{-4.09} \quad \dots 7.11$$

The Radiation manual gives the relation as:

$$a_R(\lambda) = \frac{P}{P_0} \cdot 0.00897 \lambda^{-(3.916+0.074\lambda+0.050/\lambda)}$$

where, P is the atmospheric pressure at the place and P_0 is 1013.25 hPa.

7.8 Aerosol Scattering:

The scattering function in a turbid atmosphere becomes more complicated. The variations in the size distribution of dust particles cause considerable changes in the

scattering properties and they are wavelength dependent also. With broadband pass glass filters, spectral irradiances could be measured in broadbands. These measurements, when used up to red wavelengths (up to 630 nm), can be used to calculate the Ångström turbidity coefficient β given by:

$$a_D(\lambda) = \beta \lambda^{-\alpha} \quad \dots 7.12$$

where, α is the wavelength exponent. Ångström used a mean value of $\alpha = 1.3$. This was later recommended by WMO for network use and adopted for the Indian network measurements.

Thus, when direct solar irradiances are measured in the total spectrum and with RG₂ filter (in the band width 630-2800 nm):

$$S_{t2} = \frac{1}{1 - \left(\frac{R}{R_0}\right)^2} \int_{300}^{630} S_{0\lambda} \left\{ e^{-m \cdot 0.00897 \lambda^{-4.09}} - m_h \beta \lambda^{-1.3} \right\} d\lambda \quad \dots 7.13$$

where, S_{t2} is the direct solar irradiance in the wavelength range 300-630 nm, 'm' is given by $m_h (P/P_0)$ and m_h is computed from equations 7.5 and 7.9.

The wavelength exponent ' α ' normally varies from 0 to 4. When small particles are predominant, α tends towards 4 and when large particles are much more in quantity, α tends to 0. When the particles are too big, the scattering becomes neutral and only reflection takes place.

7.9 Determination of wavelength exponent ' α '

Ångström had used the mean value of 1.3 for α which will be grossly in error in a case where the density of particulate matter suspended in the air is higher as is the case in an industrially developed location or sites in arid and semi-arid regions. Ångström (Ref.6) has suggested the use of three standard band pass filters for the actual determination of the wavelength exponent α and then of the turbidity coefficient.

The attenuation a_{λ_1} and a_{λ_2} at two wavelengths λ_1 and λ_2 are related to $\alpha = 1.3$ and β by the following relationship:

$$a_{\lambda_1} = \exp\left(-m\beta_g / \lambda_1^{1.3}\right) = \exp\left(-m\beta_0 / \lambda_1^{\alpha_0}\right) \quad \dots 7.14$$

$$\text{and } a_{\lambda_2} = \exp^{(-m\beta_{rr}/\lambda_2^{1.3})} = \exp^{(-m\beta_0/\lambda_2^{\alpha_0})} \quad \dots 7.15$$

Here, β_g and β_{rr} refer to turbidity coefficients for wavelength range 525 – 630 nm and 630 - 710 nm respectively. α_o and β_o are the true values α and β .

We then have

$$\alpha_o = 1.3 - 6.02 \log \frac{\beta_{rr}}{\beta_g} \quad \dots 7.16$$

$$\text{and } \log \frac{\beta_{rr}}{\beta_o} = (1.3 - \alpha_o) \log \lambda_2 \quad \dots 7.17$$

Here, λ_1 is taken as 0.454 μm and λ_2 as 0.669 μm . To enable quick determination of β_{rr} and β_g , Ångström constructed appropriate nomograms.

7.10 Linke Turbidity Factor 'T'

To get the total attenuation factor over the entire solar spectral range, Linke and Boda expressed the mean extinction coefficient as the total attenuation due to molecular scattering by pure air and averaged over the entire spectrum. This mean extinction coefficient is termed the Linke turbidity factor 'T'. The factor T defined initially was found to be highly sensitive to ozone and water vapour in the atmosphere. The revised relation after applying corrections is given as:

$$S_m = S_o e^{-\sigma(m)T} \int_0^\infty S_{o\lambda} e^{-\sigma_\lambda m} \left(\frac{1 + a_{\lambda w} + d\sigma_{\lambda d}}{\frac{P}{P_0} \sigma_\lambda} \right) d\lambda \quad \dots 7.18$$

Here, S_m is the measured direct solar irradiance

$$m \text{ is optical air mass} = m_h \frac{P}{P_o}$$

σ_λ (m) is Rayleigh scattering coefficient at optical path length m and is given by
 $0.00386 \lambda^{-4.09}$

m_h is relative air mass

$a_{\lambda w}$ is extinction due to water vapour absorption

$\sigma_{\lambda d}$ is extinction due to aerosol scattering

By definition T is never less than unity. T, therefore, is a measure of atmospheric turbid condition.

7.11 Aerosol Optical Depth

The aerosol optical depth is the term used for atmospheric turbidity when monochromatic irradiance or irradiances in very narrow wavelength ranges are involved. Normally the aerosol optical depth is used to denote the total extinction by scattering and absorption by aerosols. Besides the particulate matter, other atmospheric constituents also attenuate the incident irradiation. Some of the constituents are ozone, carbon dioxide, water vapour and nitrogen dioxide. By choosing appropriate wavelengths, their effect can easily be studied. The measurements in narrow spectral ranges are made using sunphotometer having very narrow band filters. Measurements made using sunphotometers and the determination of the optical depth are grouped together and called sunphotometry.

If a monochromatic radiant energy field having water vapour absorption is considered, the Beer's law will give spectral extinction coefficient due to absorption and scattering processes. The irradiance is expressed by:

$$S_{\lambda} = S_{0\lambda} e^{\tau_{\lambda} m} \quad \dots 7.19$$

where, τ_{λ} is the extinction coefficient.

Expressing the logarithmic base to 10 instead of 'e', this becomes,

$$S_{\lambda} s = S_{0\lambda} 10^{-m\tau_{R\lambda} - m\tau_{Z\lambda} - m_h\tau_{a\lambda}} \quad \dots 7.20$$

where, s is correction factor for sun-earth distance

$\tau_{R\lambda}$ is the extinction due to Rayleigh atmosphere

$\tau_{Z\lambda}$ is the extinction due to ozone

$\tau_{a\lambda}$ is the extinction due to aerosols

In sunphotometry, the irradiance values are not normally derived. Instead, the actual instrument reading (e.g. in volts) denoted by J is used. Then equation 7.20 is written as,

$$J_{\lambda} s = J_{0\lambda} 10^{-m\tau_{R\lambda} - m\tau_{Z\lambda} - m_h\tau_{a\lambda}} \quad \dots 7.21$$

$$\text{or } \tau_{a\lambda} = \frac{1}{m_h} \left[\log \frac{J_{0\lambda}}{J_{\lambda} s} - \frac{p}{p_0} (\tau_{R\lambda} + \tau_{Z\lambda}) \right] \quad \dots 7.22$$

In all computations Rayleigh scattering has to be taken into account.

7.12 Atmospheric Transparency or Transmission Coefficient:

The radiant energy that gets attenuated by the atmosphere and is incident on the earth's surface, also gives the degree of transparent nature of the atmosphere under different conditions. If S_λ is the irradiance received in a given wavelength band and $S_{0\lambda}$ the corresponding extraterrestrial irradiance, then the transmission coefficient (q_λ) is given by:

$$S_\lambda = S_{0\lambda} (q_\lambda)^m \quad \dots 7.23$$

where, m is the optical air mass at the time of measurement. From the spectral irradiance values outside the earth's atmosphere, available in literature (Radiation Manual of WMO), the total irradiance in any specific spectral band can be extracted and used in the equation 7.23. S_λ is measured with a pyrheliometer with suitable filters. Hence q_λ can be derived. q can be for irradiation for a specific bandwidth or for the entire solar irradiation range. The transparency of the atmosphere is a vital input parameter in many atmospheric modelling works and connected studies.

7.13 Shading ring correction:

Diffuse irradiance measurements are done using a shading disc or a shading ring (shadow band) device. When a shading disc is used, it has to move along with the apparent motion of the sun, so that the shadow of the disc always covers fully the outer glass hemisphere of the pyranometer. Then the disc has to be mounted on an equatorial mount and electrically driven synchronous with the sun. This, however, requires regular checks for the correct shadow position. As this is not so easily achieved on a network scale, shading ring methods are used. However, a shading ring unnecessarily cuts off a significant part of the sky and hence the diffuse irradiances from those parts. Therefore, a correction is to be applied to get the true diffuse irradiances.

The Indian network uses a correction factor derived by A.J. Drummond (Ref.18) for the Schüepp type of shading ring arrangement. The correction factor is worked out from:

$$\frac{X}{T} = \frac{2b}{\pi} \cos^3 \delta (\sin \phi \sin \delta \times t_0 + \cos \phi \cos \delta \cos t_0) \quad \dots 7.24$$

where, X is the irradiance on the receiver plane occluded by the ring

T is the irradiance from the whole hemisphere

b is the breadth of the shadow ring

r is the radius of the shadow ring

δ is the declination of the sun

ϕ is the latitude of the place of measurement

t_0 is the hour angle of the sun at sunrise or sunset

t_0 corresponds to half of the duration of the day which is the duration between sun rise and sunset.

If $E_{dm} \downarrow$ is the irradiance measured by the pyranometer covered with the shading ring and if $E_d \downarrow$ is the actual value then $E_d \downarrow$ is given by,

$$E_d \downarrow = \frac{E_{dm} \downarrow}{1 - \frac{X}{T}} \quad \dots 7.25$$

The correction factor is $1/[1-(X/T)]$ for a sky of uniform brightness and where b is small compared to ' r '. The correction factors lie approximately within 4-8 per cent. The factor is minimum in January and maximum in April and September with a secondary minimum in July.

The above derivation of correction is based on the assumption that the scattered radiant energy is isotropic. This is not a valid assumption as it is highly anisotropic even under cloudless or overcast sky conditions. The diffuse irradiance, it is found, is maximum within an angular radius of 30° around the sun. The anisotropic nature of the diffuse irradiance changes with the turbidity of the air and with cloudy conditions. The relation $E_d \downarrow / E_g \downarrow$ will be an indicator of the general atmospheric turbidity condition.

7.14 Irradiation on Inclined Surfaces:

Normally radiation measurements are made with the sensors in a horizontal position as in the case of pyranometer, pyrriadiometer or pyrgeometer and at normal incidence when direct solar irradiances are required. But for solar energy applications the receiving surfaces are normally kept in a tilted position to maximize capture of solar energy incident on it. Similar is the case in few of agricultural and engineering studies. Since most of the data are for climatological purposes, they are recorded by sensors kept in a horizontal position. Hence it is necessary to derive the values of radiant energy falling on inclined surfaces from the values of direct and global solar irradiances. Several workers have worked out the values on inclined surfaces by using empirical relations. Some of them are given below.

[illegible]

δ = Declination of the sun
 A = Azimuth of the sun

B = Azimuth of the inclined surface
 β = Angle of inclination of the surface with the horizontal
 So = Extra terrestrial direct solar irradiance
 S = Direct solar irradiance received at the earth's surface
 i = Angle of incidence, on the slope, of solar irradiation
 h = Solar elevation angle
 Z = Solar zenith angle
 m = Optical air mass
 $E_{g\downarrow}$ = Global solar irradiance on the horizontal surface
 $E_{gs\downarrow}$ = Global solar irradiance on the inclined surface
 $E_{d\downarrow}$ = Diffuse solar irradiance on the horizontal surface
 $E_{ds\downarrow}$ = Diffuse solar irradiance on the inclined surface
 S_h = Direct solar irradiance on the horizontal surface
 S_s = Direct solar irradiance on the inclined surface
 α = Albedo of the underlying surface
 ϕ = Latitude of the place
 $E_r\uparrow$ = Reflected solar irradiance
 $E_{rs}\uparrow$ = Reflected solar irradiance on the inclined surface
 t = Hour angle of the sun

7.15 Relationships given by IMD (Ref.31):

The total solar irradiance ($E_{gs\downarrow}$) falling on an inclined surface has three components
 - the direct solar irradiance S_s , the diffuse irradiance $E_{ds\downarrow}$ and reflected solar irradiance $E_{rs}\uparrow$

$$E_{gs\downarrow} = S_s + E_{ds\downarrow} + E_{rs}\uparrow \quad \dots 7.26$$

$$S_s \text{ is expressed as } S_s = \frac{S_h \cos i}{\cos z} = \frac{S_h \cos i}{\sin h} \quad \dots 7.27$$

$$\text{where, } \cos i = \cos \beta \cos z + \sin \beta \sin z \cos (A-B) \quad \dots 7.28$$

$$\cos A = \frac{\sin \phi \cos z - \sin \delta}{\cos \phi \sin z} \quad \dots 7.29$$

$$\sin h = \cos z = \sin \phi \sin \delta + \cos \phi \cos \delta \cos t \quad \dots 7.5$$

S_s will tend to be very high as $\cos z \rightarrow 0$ at sunrise or sunset time. IMD computed the values of S_s leaving the first and last hours of the daytime.

The diffuse component $E_{ds}\downarrow$ is given by

$$E_{ds}\downarrow = E_d\downarrow \left(\frac{S_h}{\cos z \cdot S_o} \right) \cos i + E_d\downarrow \left[1 - \left(\frac{S_h}{\cos z \cdot S_o} \right)^{1/m} \cdot \cos z \right] \left(\frac{1 + \cos s}{2} \right) \quad \dots 7.30$$

The reflected component $E_{rs}\uparrow$ is expressed by

$$E_{rs}\uparrow = \frac{E_g\downarrow \cdot \alpha (1 - \cos \beta)}{2} \quad \dots 7.31$$

The above relations were adapted from Hay (1977) with the assumption that the scattering is isotropic in the atmosphere.

7.16 Expressions used by Mani (Ref.40):

Direct Solar Irradiance S_s is given by

$$S_s = S \cdot \cos i \quad \dots 7.32$$

$$\cos i = \cos \beta \sin h + \sin \beta \cos h \cos (A-B)$$

$$\sin h = \sin \phi \sin \delta + \cos \phi \cos \delta \cos t$$

$$\cos (A-B) = \frac{\sin \phi \cos \delta \cos t - \cos \phi \sin \delta}{\cos h} \quad \dots 7.33$$

When $\beta = 0$, the surface is horizontal, then

$$S_s = S_h = S \cdot \sin h \quad \dots 7.34$$

$$K_l = \frac{S_s}{S_h} = \text{The tilt factor} \quad \dots 7.35$$

$$S_h = E_g\downarrow - E_d\downarrow \quad \dots 7.36$$

In general, K_l can be expressed as $\frac{S_s}{S_h} = \frac{S \times \cos i}{S \times \sin h} = \frac{\cos i}{\sin h}$

$$\therefore K_l = \cos \beta + \frac{\sin \beta \cos (A-B)}{\tan h} \quad \dots 7.37$$

Diffuse component:

$$E_{ds}\downarrow = E_d\downarrow \frac{1 + \cos \beta}{2} \quad \dots 7.38$$

Reflected component:

$$E_{rs}\uparrow = E_r\uparrow \left(\frac{1 - \cos \beta}{2} \right) = \alpha E_g\downarrow \left(\frac{1 - \cos \beta}{2} \right) \quad \dots 7.39$$

Global irradiance $E_{gs}\downarrow$ is therefore given by:

$$E_{gs}\downarrow = K_l S_h + \left(\frac{1 + \cos \beta}{2} \right) E_d\downarrow + \left(\frac{1 - \cos \beta}{2} \right) E_r\uparrow \quad \dots 7.40$$

The tilt factor is given by,

$$K_l = \frac{E_{gs}\downarrow}{E_g\downarrow} = \left(1 - \frac{E_d\downarrow}{E_g\downarrow} \right) K_l + \left(\frac{1 + \cos \beta}{2} \right) \frac{E_d\downarrow}{E_g\downarrow} + \alpha \left(\frac{1 - \cos \beta}{2} \right) \quad \dots 7.41$$

Mani calculated the tilt factor for ϕ , $(\phi+15)$ and $(\phi-15)$, $\beta = 22.5^\circ$ and $\beta = 90^\circ$ for south facing surface with $A = \pm 15^\circ, \pm 30^\circ, \pm 45^\circ$,

7.17 Expressions given by Goswami et. al. (Ref.65):

$$S_h = S \cos i$$

$$\cos i = \cos h \cos (A-B) \sin \beta + \sin h \cos \beta$$

$$E_{ds}\downarrow = E_d\downarrow \left(\frac{1 + \cos \beta}{2} \right)$$

$$E_r\uparrow = \alpha E_g\downarrow$$

$$E_{rs}\uparrow = \alpha E_g\downarrow \left(\frac{1 - \cos \beta}{2} \right)$$

It is seen that most of the variations in the expressions are found in evaluating the value of

$$E_{ds}\downarrow \quad \text{Liu and Jordan (Ref.39(a)) used } E_{ds}\downarrow = E_d\downarrow \left(\frac{1 + \cos \beta}{2} \right)$$

Temps and Coulson (Ref.59) used

$$E_{ds}\downarrow = E_d\downarrow \left(\frac{1 + \cos \beta}{2} \right) \left(1 + \sin^3 \frac{\beta}{2} \right) \left(1 + \cos^2 i \sin^3 z \right) \quad \dots 7.42$$

Klucher (Ref.36) used

$$E_{ds}\downarrow = E_d\downarrow \left(\frac{1 + \cos \beta}{2} \right) \left(1 + F \sin^3 \frac{\beta}{2} \right) \left(1 - F \cos^2 i \sin^3 z \right) \quad \dots 7.43$$

$$\text{where, } F = 1 + \left(\frac{E_d\downarrow}{E_r\uparrow} \right)^2$$

Hay and Davies (Ref.28) used

$$E_{ds} \downarrow = E_d \downarrow \left\{ \left(S \cos i / S_o \cos z \right) + \frac{1}{2} (1 + \cos \beta) \left(1 - \frac{S}{S_o} \right) \right\} \quad \dots 7.44$$

S_0 is corrected value for sun-earth distance.

In all the cases the azimuth angles are positive in the clockwise direction from the South and negative in the anticlockwise direction. Thus East facing wall will have an azimuth angle of -90° .

7.18 Kondratyev's (Ref.37) Expression:

Direct solar irradiation on an inclined surface is given by $S_s = S \cdot \cos i$

$$\begin{aligned} \cos i &= \cos \beta \sin h + \sin \beta \cos h \cos (A-B) \\ \sin h &= \sin \phi \sin \delta + \cos \phi \cos \delta \cos t \\ \cos A &= \frac{\sin h \sin \phi - \sin \delta}{\cos h \cos \phi} \end{aligned} \quad \dots 7.45$$

$$\sin A = \frac{\cos \delta \cos t}{\cos h} \quad \dots 7.46$$

Global irradiance $E_{gs} \downarrow$ can be worked out from

$$E_{gs} \downarrow = S [\cos \beta \sin h + \sin \beta \{ \cos B \sin h - \sin \delta \sin \phi + \sin B \cos \delta \sin t \}] \quad \dots 7.47$$

For a horizontal surface, $\beta = 0$ then

$$E_g \downarrow = S \cos z = S \cdot \sin h \quad \dots 7.48$$

For a vertical surface, $\beta = \pi/2$.

$$E_{gv} \downarrow = S \cos h \cos (A-B) \quad \dots 7.49$$

For a south facing vertical surface, $\beta = 0$ then

$$E_{gvs} \downarrow = S \cos h \cos A \quad \dots 7.50$$

For East/West facing vertical surface, $\beta = \pi/2$.

$$\text{Then, } E_{gv(E/S)} = S \cos \delta \sin t = S \cos h \sin A \quad \dots 7.51$$

For a North facing surface, $\beta = 180^\circ$

$$\text{Then, } E_{gvN} \downarrow = S (\sin \delta \cos \phi - \cos \delta \sin \phi \cos t) \quad \dots 7.52$$

Thus $E_{gv} \downarrow$ can be written as

$$E_{gv} \downarrow = E_{gvs} \downarrow \cos B + E_{gv} \downarrow_{E/W} \sin B \quad \dots 7.53$$

For an inclined surface facing a cardinal direction $E_{gs} \downarrow$ can be written as

$$E_{gs\downarrow} = E_g\downarrow \cos \beta + E_{gv\downarrow} \sin \beta \quad \dots 7.54$$

$$\text{or } E_{gs\downarrow} = E_g\downarrow \cos \beta + [E_{gvs\downarrow} \cos i + E_{gv(E/W)\downarrow} \sin i] \sin \beta \quad \dots 7.55$$

7.19 Klein's treatment (Ref.35):

Klein gave the following method for deriving the monthly average irradiation on tilted surfaces.

$$\overline{K_T} = \frac{\overline{H_g\downarrow}}{\overline{H_{go}\downarrow}} \quad \dots 7.56$$

Here $\overline{H_g\downarrow}$ is the mean daily global irradiation and $\overline{H_{go}\downarrow}$ is the mean daily extraterrestrial irradiation on a horizontal surface.

Mean daily irradiation on a tilted surface $\overline{H_{gs\downarrow}}$ can be expressed by:

$$\overline{H_{gs\downarrow}} = \overline{R} \overline{H_g\downarrow} = \overline{R} \overline{K_T} \overline{H_{go}\downarrow} \quad \dots 7.57$$

where, \overline{R} is the ratio of mean daily irradiation on a tilted surface and mean daily global irradiation.

$$\begin{aligned} \overline{R} &= \overline{H_{gs\downarrow}} / \overline{H_g\downarrow} \\ &= \left(1 - \frac{\overline{H_d\downarrow}}{\overline{H_g\downarrow}}\right) \overline{R_b} + \frac{\overline{H_d\downarrow} (1 + \cos \beta)}{\overline{H_g\downarrow} 2} + \frac{\alpha (1 - \cos \beta)}{2} \end{aligned} \quad \dots 7.58$$

Here, $\overline{H_d\downarrow}$ is the monthly mean daily diffuse irradiation.

$\overline{R_b}$ is the ratio of monthly mean beam irradiation on the tilted surface to the mean global solar irradiation for each month.

Liu and Jordan (Ref.39 (a)) had suggested that $\overline{R_b}$ can be derived from the extraterrestrial irradiation on an inclined surface and corresponding value on a horizontal surface for each month.

For surfaces facing equator,.

$$\overline{R_b} = \frac{\cos(\phi - \beta) \cos \delta \sin t'_s + \frac{\pi}{180} t'_s \sin(\phi - \beta) \sin \delta}{\cos \phi \cos \delta \sin t_s + \frac{\pi}{180} t_s \sin \phi \sin \delta} \quad \dots 7.59$$

where, 't' is in degrees (afternoons are taken as positive)

t'_s is sunset hour angle for the tilted surface.

This is given by:

$$t'_s = t_s \quad \text{at sunset}$$

$$\text{or } t_s' = \cos^{-1} \{-\tan(\phi - \beta) \tan \delta\}.$$

The minimum value is to be considered.

For other orientations, \bar{R}_b is determined from the apparent daytime for the tilted and differently oriented surface from extraterrestrial value, $\bar{H}_{gos} \downarrow$ and then divide it by $\bar{H}_{go} \downarrow$.

Then \bar{R}_b can be expressed in the form:

$$\begin{aligned} \bar{R}_b = & \left\{ [\cos \beta \sin \delta \sin \phi] \frac{\pi}{180} (t_{ss} - t_{sr}) - [\sin \delta \cos \phi \sin \beta \cos B] \frac{\pi}{180} (t_{ss} - t_{sr}) \right. \\ & + [\cos \phi \cos \delta \cos \beta] [\sin t_{ss} - \sin t_{sr}] + [\cos \delta \cos B \sin \phi \sin \beta] [\sin t_{ss} - \sin t_{sr}] \\ & \left. - [\cos \delta \sin \beta \sin B] [\cos t_{ss} - \cos t_{sr}] \right\} \left/ \left[2 \left\{ \cos \phi \cos \delta \sin t_s + \frac{\pi}{180} t_s \sin \phi \sin \delta \right\} \right] \right. \quad \dots 7.60 \end{aligned}$$

t_{sr} and t_{ss} are hour angles at sunrise and sunset on the tilted surface.

When $B < 0$,

$$\begin{aligned} t_{sr} &= t_s \text{ or } \cos^{-1} \left(PQ + \sqrt{P^2 - Q^2 + 1} \right) / (P^2 + 1) \text{ and} \\ t_{ss} &= t_s \text{ or } \cos^{-1} \left(PQ - \sqrt{P^2 - Q^2 + 1} \right) / (P^2 + 1) \end{aligned}$$

Only the minimum value of the two is to be used in each case (of t_{sr} or t_{ss}).

When $B > 0$,

$$\begin{aligned} t_{sr} &= -t_s \text{ or } \cos^{-1} \left(PQ - \sqrt{P^2 - Q^2 + 1} \right) / (P^2 + 1) \text{ and} \\ t_{ss} &= t_s \text{ or } \cos^{-1} \left(PQ + \sqrt{P^2 - Q^2 + 1} \right) / (P^2 + 1) \end{aligned}$$

$$\text{Here } P = \cos \phi / (\sin B \tan \beta) + \frac{\sin \phi}{\tan B} \text{ and}$$

$$Q = \tan \delta \left[\frac{\cos \phi}{\tan B} - \frac{\sin \phi}{\sin B \tan \beta} \right] \quad \dots 7.61$$

If reflectivity of the surface is isotropic, then reflected solar irradiance is given by:

$$H_{Rs} \uparrow = H_g \downarrow \alpha (1 - \cos \beta) / 2 \quad \dots 7.62$$

The diffuse solar irradiance is expressed as:

$$H_{ds} \uparrow = H_d \downarrow \frac{(1 + \cos \beta)}{2} \quad \dots 7.63$$

Then the global irradiance on a tilted surface can be written in the form:

$$H_{gs} \downarrow = [H_g \downarrow - H_d \downarrow] R_b + H_g \downarrow \alpha (1 - \cos \beta) / 2 + H_d \downarrow (1 + \cos \beta) / 2 \quad \dots 7.64$$

7.20 Estimations using empirical relations:

The solar radiation measurements on a network scale are scarce, especially in earlier days. Even the existing networks cannot be taken to be adequate as there are significant gaps, especially in big countries like India. It is natural to resort to modelling and empirical relations based on data on duration of sunshine and other meteorological parameters. The first such attempt was made by Ångström who used available mean monthly solar radiant exposure values on cloudless days and duration of bright sunshine.

There are several approaches in deriving the global irradiances. Broadly grouped, they fall into three models: (i) sunshine duration model, (ii) cloud layer model and (iii) models based on extraterrestrial values and radiative properties of atmospheric constituents. Although they are all based on scientific and logical considerations, they are empirical in nature. A brief account of these methods is given below:

7.20.1 Models based on sunshine data:

Since sunshine recorders are in use for longer periods and at more number of places, early attempts to derive the irradiance values were all based on the duration of sunshine hours. The first work was by Ångström (Ref.5) who gave an empirical relation in the form:

$$E_g \downarrow = E_{gc} \downarrow \left[a_1 + (1-a_1) \frac{n}{N} \right] \quad \dots 7.65$$

Here, $E_{gc} \downarrow$ is the global solar irradiance on a perfectly cloudless day

a_1 is an empirically determined constant equal to 0.25

n is the mean hours of duration of sunshine and

N is the possible hours of duration of sunshine which is equal to length of the day.

In view of the practical difficulties in identifying a perfectly cloudless day, Prescott (Ref.47) replaced $E_{gc} \downarrow$ by $E_g^s \downarrow$, the extraterrestrial global solar irradiance and gave a new relationship

$$E_g \downarrow = E_g^s \downarrow \left[a + b \frac{n}{N} \right] \quad \dots 7.66$$

where, 'a' and 'b' are regression constants.

$E_g^s \downarrow$ can be derived from:

$$E_g^s \downarrow = S_0 \left(\frac{R_o}{R} \right)^2 [\cos \phi \cos \delta \sin t_o + t_o \sin \phi \sin \delta] \quad \dots 7.67$$

where, t_o is the hour angle at sunrise or sunset. Most of the investigations using this regression method gave values ranging from 0.14 to 0.54 for 'a' and 0.18 to 0.73 for 'b'. It may be seen that for an overcast day $E_{g\downarrow} = E_{g^s\downarrow} \times a$. The constant 'b', therefore, indicates that increases in $E_{g\downarrow}$ are linked with the increases in the ratio n/N . Under ideal clear and cloudless sky, $n = N$ and hence $E_{g\downarrow} = E_{g^s\downarrow} [a + b]$. Then $(a + b)$ is nearly the transmission factor of the atmosphere. Thus, the value of 'a' depends on the cloud types and of 'b' on the turbidity and water vapour content of the atmosphere. It is found that the values of a and b show changes from place to place.

There are several works to reduce the error/uncertainty in the values of $E_{g\downarrow}$ derived. **Rietveld** (Ref.50) suggested that a and b may be expressed as:

$$a = 0.10 + 0.24 \frac{n}{N} \quad \dots 7.68$$

$$\text{and } b = 0.38 + 0.08 \frac{n}{N} \quad \dots 7.69$$

Then the revised Ångström relation becomes

$$E_g = E_{g^s\downarrow} \left[0.18 + 0.62 \frac{n}{N} \right] \quad \dots 7.70$$

Glover and McCulloch (Ref.23) introduced the variation in 'a' due to changes in latitude of the places and gave an expression for 'a' as:

$$a = 0.01 + 0.27 \cos \phi \quad \dots 7.71$$

and revised the Ångström relation to

$$E_{g\downarrow} = E_{g^s\downarrow} \left[0.29 \cos \phi + 0.52 \frac{n}{N} \right] \quad \dots 7.72$$

Gopinathan (Ref.24,25) taking altitude also into consideration gave the expressions for 'a' and 'b' as:

$$a = -0.309 + 0.539 \cos \phi - 0.0693 h + 0.290 \frac{n}{N} \quad \dots 7.73$$

$$\text{and } b = 1.527 - 1.027 \cos \phi + 0.0926 h - 0.359 \frac{n}{N} \quad \dots 7.74$$

Ögelman (Ref.43) et al proposed a quadratic relationship with $\frac{n}{N}$ in the form

$$E_{g\downarrow} = E_{g^s\downarrow} \left[0.195 + 0.676 \frac{n}{N} - 0.142 \left(\frac{n}{N} \right)^2 \right] \quad \dots 7.75$$

He expressed 'a' and 'b' as:

$$a = 0.195 + 0.142 \left(\frac{n}{N} \right)^2 \text{ and}$$

$$b = 0.676 - 0.284 \frac{n}{N}$$

This is supposed to give the best results when derived from sunshine data.

Attempts have been made to derive global solar irradiance from cloud data also. Since sunshine indirectly indicates the cloudy condition of the sky, few attempts have been made to derive the duration of sunshine from cloud data. **J. Reddy** (Ref.33) uses a relationship to give fractional sunshine in the form:

$$\frac{n}{N} = 1 - f_1 + f_2 \quad \dots 7.76$$

$$\text{where, } f_1 = a \cdot e^{-0.25\sqrt{a}}$$

a is given by $(c_l + c_m + c_h)/8$

where, c_l , c_m , and c_h are amounts of clouds (in octas) in the low, medium and high cloud strata respectively and

$f_2 = 0.02 + 0.08 \cos 4\phi$ for latitudes up to 45° and -0.06 for higher latitudes. Here, ϕ is the latitude of the place.

WMO in Technical Note No. 172 (Ref.62) lists some of the systematic errors in deriving the global solar irradiances from sunshine data. The two main errors are due to:

1. The mean cloudiness is affected only moderately during the middle parts of the day whereas the irradiance values undergo vast changes.
2. In case of fogs or other agents that cause attenuation, there is an apparent increase in cloudiness and decrease in the sunshine duration. The irradiances are not drastically altered due to this apparent cloudiness.

7.20.2 Models based on cloud layers:

Among the meteorological parameters that influence the quantity of solar irradiance, the clouds alter the field greatly. The sunshine models, as already pointed out, do not represent the ever-changing cloud type and cover. In the most general form, the global irradiation $E_g \downarrow$ can be expressed as:

$$E_g \downarrow = E_{go} \psi_c f(\alpha, \rho) \quad \dots 7.77$$

where, ψ_c is the cloud field transmittance

$f(\alpha, \rho)$ is a function of ground albedo α and atmospheric reflectivity ρ for surface reflected irradiation including multiple reflections.

The cloud field transmissivity is a function of either sunshine or cloud amount – total amount c or layer cloud amount c_i . For cloud cover, the equation may be expressed as

$$E_g \downarrow = E_{go} \downarrow (1 - c_i + t_i c_i) (1 - \alpha \rho)^{-1} \quad \dots 7.78$$

where, t_i is the cloud transmittance determined empirically. This can be obtained from the table worked out by **Haurwitz** (Table 3 of paper of **Davies and Mckay**). (Ref.16 & 17) Replacing cloud free irradiance $E_g \downarrow$ by $E_g^s \downarrow$, the extraterrestrial value $E_g \downarrow$ becomes:

$$E_g \downarrow = E_{gs} \downarrow (1 - c_i + t_i c_i) (1 - \alpha \rho)^{-1} \quad \dots 7.79$$

It is stated that the layer models (cloud layer) are best suited in principle for estimating the daily irradiance especially the hourly values. They can be used even with incomplete cloud layer data. Since cloud cover lingers longer, even synoptic data on clouds can be used. **Mani and Rangarajan** (Ref.41) gave the following equation for deriving sunshine data from total cloud amount:

$$1 - \frac{n}{N} = 0.310c + 0.476 c^2 + 0.100 c^3 \quad \dots 7.80$$

where, 'N' is duration of possible hours of sunshine between the times when solar elevation is at least 5° above the horizon in the morning and in the evening. This 5° limit they had used to account for the sufficient irradiance level from the sun to cause a record on the sunshine card.

Hay (Ref.27) used an equation given by:

$$E_g \downarrow = E_{go} \downarrow \frac{(1 - CA) + tCA}{1 - \alpha_s \bar{\alpha}_c CA} \quad \dots 7.81$$

Here, CA is total cloud amount

α_s is Surface albedo

$\bar{\alpha}_c$ is average cloud albedo

Hay had given tabulation for α_s and absorptivity. He used the following equation for diffuse component:

$$E_d \downarrow = (1 - CA) E_{do} \downarrow + CA t E_{go} \downarrow + \alpha_s G \bar{\alpha}_c CA \quad \dots 7.82$$

where, $E_{do} \downarrow$ is the diffuse solar irradiance under cloudless sky conditions. He also used the equation $S = (1-CA)S_o$ for the direct solar irradiance; S_o is the solar constant corrected for the sun-earth distance.

7.20.3 Models using solar constant only:

It is possible that the irradiance values may have to be derived for places poorly represented in the meteorological network. Knowing the coordinates of a location, it is possible to arrive at a reliable data set using the extraterrestrial irradiance values. However, in such cases approximations have to be made for the Rayleigh scattering, the aerosol scattering, the individual absorption due to water vapour, carbon dioxide, ozone and oxygen and for the reflectivity of different surfaces.

There are several works to deduce global and diffuse irradiances from the values of extraterrestrial irradiances. The works of Paltridge and Proctor (Ref.46), Albrecht (Ref.2), Braslau and Dave (Ref.8), Katayama (Ref.34), Sasamori et al (Ref.54), Hoyt (Ref.29) and Graham and Hollands (Ref.26) are few of the several significant ones in this field. Braslau and Dave model is most detailed using radiative transfer models. They are, however, very involved. Similar is the case with Graham and Hollands model who used stochastic procedures for generating synthetic hourly global solar irradiances. All the models use the atmospheric transmittance as the basic parameter to be worked out.

Sufficiently good results are obtained by using the Hoyt model (Ref.29) which is briefly given below:

The atmospheric transmission or transmittance is defined as the ratio of the global solar irradiance at the surface of a locale to the corresponding extraterrestrial value. This is also sometimes referred to as the clearness index. This transmission depends on the relative strength of scattering processes and the absorption processes that interact with the irradiation in its passage through the atmosphere. The constituents that dominate the scattering processes are the air molecules and the aerosol particles. If the scattering function is denoted by σ , then σ_R is the scattering function due to air and σ_d is the scattering function due to aerosol particles.

Hoyt expressed σ_R to be

$$\sigma_R = 1 - f(m^*)^{m^*} \quad \dots 7.83$$

where, m^* is the optical air mass corrected for pressure. Hoyt gives a table connecting $f(m^*)$ with m^* .

The expression for σ_d is given by:

$$\sigma_d = 1 - g(\beta)^{m^*} \quad \dots 7.84$$

where, β is the Ångström turbidity coefficient or aerosol optical depth at $1\mu\text{m}$. This optical depth τ_d is given by $\tau_d = \beta \lambda^{-\alpha}$ where α is the wavelength exponent which was 1.3 as used by Ångström. Hoyt assumed a value of 1.0 for α and calculated the function of $g(\beta)$ and gave it in the form of a table.

The major contributors for absorption processes are water vapour, carbon dioxide, ozone, oxygen and aerosol particles. The absorptivity or the absorption functions are then represented by:

a_1 due to water vapour, a_2 due to carbon dioxide, a_3 due to ozone, a_4 due to oxygen and a_5 due to aerosol particles.

Hoyt gave the following expressions:

$$a_1 = 0.110 (u_1 + 6.31 \times 10^{-4})^{0.3} - 0.0121$$

where, u_1 is the total precipitable water in gcm^{-2} in the atmospheric path and corrected for pressure.

$$a_2 = 0.00235 (u_2 + 0.0129)^{0.26} - 7.5 \times 10^{-4}$$

where, u_2 is the path length of carbon dioxide after correction for pressure. In view of near stability in the concentration, this is assumed to be 126 cm at standard temperature and pressure (STP) and at $m=1$.

$$a_3 = 0.045 (u_3 + 8.34 \times 10^{-4})^{0.38} - 3.1 \times 10^{-3}$$

where, u_3 is the ozone path length in cm at STP

$$a_4 = 7.5 \times 10^{-3} (m^*)^{0.875}$$

$$a_5 = (1-\rho) g(\beta)^{m^*}$$

where, ρ is the albedo due to single scattering and assumed it to be 0.95 .

Hoyt uses the following expression to work out the direct solar irradiance on a horizontal surface:

$$S_h = S_0 \cos z \left\{ 1 - \sum_{i=1}^5 a_i \right\} (1 - \sigma_R)(1 - \sigma_d) \quad \dots 7.85$$

The diffuse solar irradiance is expressed as:

$$E_d \downarrow = S_0 \cos z \left\{ 1 - \sum_{i=1}^5 a_i \right\} (0.5\sigma_R + 0.75\sigma_d) \quad \dots 7.86$$

S_0 here is the extraterrestrial irradiance corrected for sun-earth distance and z is the zenith angle. He proposed that one-half of the Rayleigh scattering (σ_R) and three fourths of the aerosol scattering (σ_d) to be in the forward direction, contributing to $E_d \downarrow$. The multiple reflections arising out of the irradiance reflected from the ground gives an added value to $E_g \downarrow$. This value $E_{rr} \downarrow$ (re- reflected) is expressed by:

$$E_{rr} \downarrow = E_r \uparrow \left(1 - \sum_{i=1}^5 a'_i \right) (0.5\sigma'_a + 0.75\sigma'_d) \quad \dots 7.87$$

σ'_a and σ'_d are calculated for 1.66 times the zenith air mass (local solar noon) for the Lambert reflectivity of the surface and a'_i , the absorptivities are evaluated for air mass values of $m^* + 1.66 \left(\frac{P}{P_o} \right)$.

The global solar irradiance $E_g \downarrow$ that reaches the earth's surface at any instant is then given by:

$$E_g \downarrow = S_h + E_d \downarrow + E_{rr} \downarrow \quad \dots 7.88$$

The transmission of the atmosphere is then $\tau = E_g \downarrow / (S_0 \cos Z)$

Hoyt gives the methods of computing $E_g \downarrow$ for cloudless and overcast sky conditions.

Mani and Rangarajan (Ref.41) used the data for ozone and precipitable water vapour, collected by the India Meteorological Department. Similarly, turbidity values obtained in the radiation network was used. They found that β values obtained during the pre-monsoon period to be low as the circumsolar irradiance during this period, though very high, was not accounted for, in calculating β . They used an expression:

$$\frac{E_d \downarrow}{S_h} = \frac{(0.75\sigma_d + 0.5\sigma_R)}{(1 - \sigma_d)(1 - \sigma_R)} \quad \dots 7.89$$

and obtained a more realistic set of values vis-à-vis measured values.

7.21 Estimating diffuse irradiances:

The measurement of global solar irradiation is more widespread in the networks. Because of the attended operational problems, diffuse solar irradiation is not measured as a routine in many places. However, with increasing awareness of its importance, several attempts have been made to estimate the diffuse irradiance values from global irradiances and sunshine duration data. Few of such attempts are outlined below:

1. **Coppolino** (Ref.15) gave an expression based on sunshine and minimum optical air mass.

$$E_d \downarrow = 7 \left(\frac{n}{N} \right)^{-0.25} (\sin h_n)^{1.55} \quad \dots 7.90$$

where, $E_d \downarrow$ is monthly mean of daily diffuse irradiation and h_n is the noon altitude in degrees of the sun on the 15th of each month. This equation was based on the radiation data recorded in Italy.

2. **Mani and Rangarajan** (Ref.41) used the empirical relationship:

$$E_d \downarrow = E_g \downarrow \left(c + d \frac{E_g \downarrow}{E_{g0} \downarrow} \right) \quad \dots 7.91$$

where, $E_{g0} \downarrow$ is the solar irradiance on a horizontal surface at the top of the atmosphere & 'c' and 'd' are regression constants.

3. **Iqbal** (Ref.32) used expressions:

$$E_d \downarrow = E_g \downarrow \left(a_1 + a_2 \frac{n}{N} \right) \text{ and } E_d \downarrow = E_{g0} \downarrow \left\{ a_1 + a_2 \frac{n}{N} + a_3 \left(\frac{n}{N} \right)^2 \right\} \quad \dots 7.92$$

where, a_1 , a_2 and a_3 are constants.

4. The expression proposed by **Liu and Jordan** (Ref.39(a)) is:

$$\tau_d = 0.2710 - 0.2939\tau_D$$

where, $\tau_d = E_d \downarrow / E_{g0} \downarrow$ and $\tau_D = E_g \downarrow / E_{g0} \downarrow$...7.93

They found τ_d to vary very moderately on the air mass and hence they neglected the airmass functions for applications where high degree of accuracy is not required. They gave the probable error from this computation to be 0.0052.

They also gave another expression:

$$\tau_d = 0.384 - 0.416 \tau_T$$
 ...7.94

where, $\tau_T = \frac{E_g \downarrow}{E_{g0} \downarrow}$

For obtaining monthly mean daily totals of diffuse irradiation, **Liu and Jordan** proposed two normalized coordinates K_d and K_T given by:

$$K_d = \frac{H_d \downarrow}{H_{g0} \downarrow} \text{ and } K_T = \frac{H_g \downarrow}{H_{g0} \downarrow}$$
 ...7.95

where, H stands for daily totals of solar irradiation, global and diffuse.

They proposed $K_d = 0.2710 - 0.2939K_D$...7.96

where, $K_D = K_T - K_d$

As cloudiness increases $K_T \rightarrow K_d$ and $K_D \rightarrow 0$

5. **Page** (Ref.45) used an expression

$$E_d \downarrow = E_g \downarrow (1.00 - 1.13 K_t) \dots\dots\dots$$
 ...7.97

where, $K_t = \frac{E_g \downarrow}{E_{g0} \downarrow}$

6. **Hay** (Ref.27) used only sunshine data, albedo of the surface and the atmospheric back scatterance. His expression takes the form:

$$\frac{E_d \downarrow}{E_g' \downarrow} = 1.7274784 - 3.5203489 \left(\frac{E_g' \downarrow}{E_g \downarrow} \right) + 1.7515141 \left(\frac{E_g' \downarrow}{E_g \downarrow} \right)^2 \quad \dots 7.98$$

where, $E_g' \downarrow = E_g \downarrow (1 - \alpha\beta)$

where, α is the albedo of the surface and β is the atmospheric back scatterance.

$E_g \downarrow$ is derived from:

$$E_g \downarrow = E_{g_0} \downarrow \left(a + b \frac{n}{N} \right)$$

where 'a' and 'b' are regression constants.

7. **Klein** (Ref.35) had suggested a cubic relation

$$E_d \downarrow = E_g \downarrow \left[1.39 - 4.027 K_t + 5.531 K_t^2 - 3.108 K_t^3 \right] \quad \dots 7.99$$

where, $K_t = \frac{E_g \downarrow}{E_{g_0} \downarrow}$ on mean monthly values

8. **Whillier** (Ref.61) had given an expression for obtaining hourly values of irradiation from daily totals. **Liu and Jordan** (Ref.39(a)) slightly modified it to the form:

$$r_{di} = \frac{\pi}{24} \frac{\cos t_i - \cos t_s}{\sin t_s - t_s \cos t_s} \quad \dots 7.100$$

where, r_{di} is ratio of hourly to daily diffuse irradiation for a desired hour.

t_i is the hour angle in degrees

t_s is the hour angle at sunset in radians

9. The monthly mean hourly diffuse radiation for clear days as suggested by **A.I.**

Kudish, et. al (Ref.38) can be derived from

$$(H_i \downarrow)_d^{cr} = r_{di} (\overline{H})_i^{cr} \downarrow \quad \dots 7.101$$

where, $(H_i \downarrow)_d^{cr}$ is the hourly clear sky diffuse irradiation

$(\overline{H})_i^{cr} \downarrow$ is total (daily) diffuse irradiation.

They worked out the mean monthly daily fraction of diffuse irradiation in the global irradiation by computing a weighted average of the fractions derived for cloudy and clear days. The weighting factor is the number or fraction of the particular hour that is cloudy or clear.

The monthly average diffuse irradiation for a specific hour is determined from

$$(\overline{H_i \downarrow})_d = \left[\omega^{cy} (H_i \downarrow)_d^{cy} + \omega^{cr} (\overline{H_i \downarrow})_d^{cr} \right] / (\omega^{cy} + \omega^{cr}) \quad \dots 7.102$$

where, ω^{cy} is weighting factor for cloudy days ω^{cr} is weighting factor for clear days.

10. **Erbs, Klein and Duffie** (Ref.20) reviewed the determination of the values of hourly, daily and monthly irradiation by various workers and derived a new relationship for them as indicated below:

They used following relationship in their work.

$$\kappa_T = \frac{E_d \downarrow}{E_g \downarrow} \text{ for hourly values, called hourly clearness index and}$$

$$K_T = \frac{H_g \downarrow}{H_{g_0} \downarrow} \text{ for daily values, called daily clearness index.}$$

The proposed relation for diffuse fraction for hourly relations is:

$$\frac{E_d \downarrow}{E_g \downarrow} = 1.0 - 0.09\kappa_T \text{ for } \kappa_T \leq 0.22$$

$$\frac{E_d \downarrow}{E_g \downarrow} = 0.9511 - 0.1604\kappa_T + 4.388\kappa_T^2 - 16.638\kappa_T^3 + 12.336\kappa_T^4 \text{ for } 0.22 < \kappa_T \leq 0.80$$

$$\text{and } \frac{E_d \downarrow}{E_g \downarrow} = 0.165 \text{ for } \kappa_T > 0.80$$

...7.103

The last relationship for $\kappa_T > 0.80$ is attributed to be due to excessive clouding and resultant multiple reflections between the surface and cloud surfaces. They also found that 90% of data points lie in the limits $0.2 < \kappa_T \leq 0.80$.

For daily values, the varying path lengths of the radiant energy during the course of the year has to be taken into consideration. They grouped the hour angle (t_s) at sunset into three classes.

-Winter $t_s < 1.4208$

-Spring and autumn $1.4208 < t_s < 1.7208$

-Summer $t_s > 1.7208$

Erbs et al (Ref.20) found that the attempted correlation between $E_d\downarrow$ and $E_g\downarrow$ was different only for winter especially when K_T is > 0.45 . They ascribed the cause to dry and cleaner winter skies resulting in lower $E_d\downarrow$. They, therefore, gave two equations:

Winter when $t_s < 1.4208$

$$\frac{H_d\downarrow}{H_g\downarrow} = 1.0 - 0.2727K_T + 2.4995K_T^2 - 11.9514K_T^3 + 9.3879K_T^4 \quad \dots 7.104$$

where, $K_T < 0.715$ and $\frac{H_d\downarrow}{H_g\downarrow}$ when $K_T \geq 0.715$

Summer and spring and autumn when

$$t_s \geq 1.4208$$

$$\frac{H_d\downarrow}{H_g\downarrow} = 1.0 + 0.2832K_T - 2.5557K_T^2 + 0.8448K_T^3 \quad \dots 7.105$$

for $K_T < 0.722$ and $\frac{H_d\downarrow}{H_g\downarrow} = 0.175$ for $K_T \geq 0.722$

Monthly average (daily) values

Winter season:

$t_s \leq 1.4208$

$$\frac{\overline{H_d}\downarrow}{\overline{H_g}\downarrow} = 1.391 - 3.560\overline{K}_T + 4.189\overline{K}_T^2 - 2.137\overline{K}_T^3 \quad \dots 7.106$$

for $0.3 \leq \overline{K}_T \leq 0.8$

Non-winter periods:

$t_s > 1.4208$

$$\frac{\overline{H_d}\downarrow}{\overline{H_g}\downarrow} = 1.311 - 3.022\overline{K}_T + 3.427\overline{K}_T^2 - 1.821\overline{K}_T^3 \quad \dots 7.107$$

for $0.3 \leq \overline{K}_T \leq 0.8$

When mean monthly daily values are worked out from daily diffuse values which are obtained by using hourly values, then a non-seasonal trend was achieved by Erbs et al using the relationship:

$$\frac{\overline{H_d} \downarrow}{\overline{H_g} \downarrow} = 1.317 - 3.023\overline{K_T} + 3.372\overline{K_T}^2 - 1.769\overline{K_T}^3 \quad \dots 7.108$$

\overline{H} and $\overline{K_T}$ represent monthly mean daily values.

11. **Collares –Pereira and Rabl** (Ref.14) ,however, gave slightly different relationships:

$$\frac{\overline{H_d} \downarrow}{\overline{H_g} \downarrow} = 0.775 + 0.347\left(t_s - \frac{\pi}{2}\right) - \left[0.505 + 0.261\left(t_s - \frac{\pi}{2}\right)\right] \cos[2(\overline{K_T} - 0.9)] \quad \dots 7.109$$

Instantaneous and daily total irradiation:

$$\text{If } r_g = \frac{\overline{E_g} \downarrow}{\overline{H_g} \downarrow} \text{ for global irradiation and}$$

$$r_d = \frac{\overline{E_d} \downarrow}{\overline{H_g} \downarrow} \text{ for diffuse radiation}$$

r_d can be expressed by the equation given by Whillier and

$$r_g = \frac{\pi}{T}(a + b \cos t) \frac{\cos t - \cos t_s}{\sin t_s - t_s \cos t_s} \quad \dots 7.110$$

where $a = 0.409 + 0.5016 \sin(t_s - 1.047)$ and

$b = 0.6609 - 0.4767 \sin(t_s - 1.047)$.

The hour angles are expressed in radians. T is the length of the day i.e. 24 hours.

7.22 Algorithms for terrestrial radiant energy:

Like measurements, deriving terrestrial radiant energy from theoretical considerations is very complex. The emission and absorption of energy in this range are by substances which are in the same wavelength range and nearly at similar temperature fields as well. The emissions depend partly on the amount of the substances in the air. The gases are selective absorbers and emitters. They absorb and emit energy almost completely at selected wavelengths and practically not at all at other wavelengths. Their emittances vary with wavelengths. But among the gases that interact with the radiation field, water vapour, carbon dioxide and ozone are the more important ones. Since the concentrations of carbon dioxide and ozone do not vary significantly, their effect on the day-to-day variations in the radiant energy at the earth's surface is not much. Unless vertical profiles are to be deduced, they are neglected, leaving the water vapour as the dominant

factor which actually it is. Besides water vapour, cloud drastically changes the values of terrestrial radiant energy at any given instant. For deducing the thermal radiant energy from available meteorological data, resort is generally made to empirical equations. Some of them are outlined below.

1. Ångström (Ref.4) – This is the first attempt found in literature:

The most general form for the downward terrestrial radiant energy $E_{l_0\downarrow}$ from the atmosphere under clear sky conditions can be written as

$$E_{l_0\downarrow} = \sigma T^4 f(e) \quad \dots 7.111$$

where, T is the atmospheric temperature in kelvin, σ the Stefan-Boltzmann constant and f(e) is a function involving water vapour pressure. Ångström's equation takes the form

$$E_{l_0\downarrow} = \epsilon \sigma T^4 (A - B \cdot 10^{-Ce}) \quad \dots 7.112$$

where ϵ is the emittance of the emitting surface, A, B and C are constants and e is vapour pressure in hPa. The values differ from one investigator to another depending on how these values were derived. Literature shows a range of 0.710 to 0.820 for A, 0.148 to 0.326 for B and 0.041 to 0.094 for C.

The upward terrestrial radiation from the surface is given by $E_{\ell_0\uparrow} = \epsilon \sigma T^4$ and net terrestrial radiant energy is given by

$$E_{\ell_0}^* = \epsilon \sigma T^4 (1 - A + B \times 10^{-Ce}) \quad \dots 7.113$$

2. Brunt (Ref.10), however, found from a series of measurements that the following expression is a better fit.

$$E_{l_0\downarrow} = \epsilon \sigma T^4 (A + B\sqrt{e}) \quad \dots 7.114$$

$$\text{and } E_{\ell}^* = \epsilon \sigma T^4 (A - B\sqrt{e}) \quad \dots 7.115$$

These yielded high correlation coefficients. Here A = 0.256 and B = 0.065. However, the investigations by different workers show the values of A and B have wider ranges, A varies from 0.34 to 0.71 and B from 0.023 to 0.110. 'e' is the vapour pressure in millimetres.

3. **J.E. Mcdonald** (Ref.42) has given an expression:

$$E_{\ell}^* = \epsilon (0.165 - 0.000769 RH) \quad \dots 7.116$$

where, RH is relative humidity

4. **Swinbank** (Ref.58) gives

$$E_{\ell}^* = \epsilon (0.245 - 0.0214 \sigma T^4) \quad \dots 7.117$$

$$\text{and } E_{\ell}^* = \epsilon \sigma T^4 (1 - 9.35 \times 10^{-6} T^2) \quad \dots 7.118$$

He also gives another expression for $E_{\ell} \downarrow$ as

$$E_{\ell} \downarrow = 5.26 \times 10^{-14} T^6 \quad \dots 7.119$$

5. **Robitzsch** (Ref.51) **Equation:**

$$E_{\ell}^* = \epsilon \sigma T^4 \{1 - (c_1 p + d_1 e) T^{-1}\} \quad \dots 7.120$$

where, p is pressure, c_1 and d_1 are constants and e is vapour pressure in hPa

6. **Elsasser's** (Ref.19) **Equation:**

$$E_{\ell}^* = \epsilon \sigma T^4 (c_2 - d_2 \log e) \quad \dots 7.121$$

where, c_2 and d_2 are constants

7. **Anderson's** (Ref.3) **Equation:**

$$E_{\ell}^* = \epsilon \sigma T^4 (c_3 - c_4 e + d_3 10^{d_4 e}) \quad \dots 7.122$$

where, c_3 , c_4 , d_3 & d_4 are constants

8. **Loennquist's** (Ref.39(b)) **Equation:**

$$E_{\ell}^* = \epsilon \sigma T^4 (c_2 - d_2 \log e) \quad \dots 7.123$$

where, c_2 and d_2 are constants

9. **Budyko** (Ref.12) **(also Anderson)** (Ref.3):

$$E_{\ell}^* = \epsilon \sigma T^4 (c_5 - d_5 e) \quad \dots 7.124$$

where c_5 & d_5 are constants

- 10. Berland & Berland** (Ref.7) take surface (soil) temperature T_e into account and gives:

$$E_{\ell}^* = \sigma T^4 f(e) + \epsilon (Te^4 - T^4) \quad \dots 7.125$$

Taking the varying cloud cover also into account they gave another equation

$$E_{\ell}^* = \sigma T^4 (11.7 - 0.40e)(1 - cn) + 4\epsilon \sigma T^3 (Te - T) \quad \dots 7.126$$

Here e is in hPa, c is a constant and n is cloud cover in tenths

- 11. Budyko** (Ref.11) gave

$$E_{\ell}^* = E_{\ell o}^* (1 - cn^2) + 4\epsilon \sigma T^3 (Te - T) \quad \dots 7.127$$

However, all the corrections to the original Ångström or Brunt's equations in order to take the effect of temperature stratifications and cloud cover, do not take into account the effect of the types and thickness of clouds. At best, computations made from these equations give an idea of the possible energy levels and are no substitutes for the measured values.

Net total radiant energy Q:

This is the sum of E_g^* the net solar irradiance and E_{ℓ}^* the net terrestrial radiant energy

$$\begin{aligned} Q &= E_g^* + E_{\ell}^* \\ &= E_g^* \downarrow (1 - \alpha) + (E_{\ell} \downarrow - E_{\ell} \uparrow) \end{aligned} \quad \dots 7.128$$

where α is the albedo of the surface

FEATURES OF INDIAN CLIMATOLOGY

CHAPTER VIII

FEATURES OF INDIAN CLIMATOLOGY

Introduction:

Weather is the aggregate of the conditions of the atmosphere in terms of few specific variables at a place over a brief period of time. This occurs every day. Climate is the aggregate of the fluctuating atmospheric conditions derived from the day-to-day weather conditions over specified area during long periods of time. Thus the climate of a place is the average atmospheric condition within which there is an expectation of small changes.

The atmospheric condition is characterized by the combined effect of the various interacting components or elements, such as solar and terrestrial radiant energy, temperature, humidity, precipitation, air pressure and wind. These atmospheric conditions and in aggregate the climate of a place depend on its distance from the equator, its height from the sea level, its distance from the large water surfaces like seas and oceans, terrain, vegetative cover and the degree of human interactions with his environment. It is not proposed to deal here with any of these aspects in detail.

The weather patterns follow the sun's path during a year as it shifts from 23.5°S (Tropic of Capricorn) on December 22 to equator on March 21, to 23.5°N (Tropic of Cancer) on June 22 and then moves back to 23.5°S again on December 22. The normal distribution of wind directions over different zones on the earth is as shown in Fig. 8.1.

Fig. 8.1 : Main features of the Mean Sea Level Circulation

The wind near the surface of the earth is never steady. The direction and speed of the air in motion is dependent, to a large extent, on the atmospheric pressures at different but contiguous places which are heated unequally by the solar irradiation during the same day. The area which gets heated more will have its air rise and then spread out to areas which are colder and subside over there. This causes a decrease in the atmospheric pressure over the warmer area. The equatorial region has such a condition. The equatorial area up to 5° to the North and South of the Equator is thus under a permanent low pressure, called the equatorial trough of low or equatorial low. This low pressure area attracts wind from the North and the South. Because of the rotation of the earth and the associated viscous drag on the air close to the surface of the earth, the air flow gets deflected towards the right in areas to the north of the Equator and towards the left in areas to the south. These winds blow from NE in the north and SE in the south of the equator and are called north-easterly trade winds (trades) and south-easterly trade winds (trades) respectively. The deflecting effect is called 'coriolis effect'.

Most of the warm air that rises over the equator subsides over 30° latitude of both hemispheres, the subtropical latitudes, giving rise to subtropical high pressure belt. Apart from this, high pressure area blows as trade winds to lower latitudes and the other part blow as westerlies as we move away from 30° latitude towards the Pole. Because of the intense cold conditions over the pole, the cold air sinks and blows from the polar circles towards the subpolar low pressure regions. However, all these low pressure and high pressure belts shift to North or South along with the sun's apparent movements through a year. This gives rise to different types of weather patterns and governed, in addition, by the unequal heat capacities of water surface (oceans) and land masses (with its varying terrain topography) and the ocean currents. This gives rise to seasonal wind patterns over vast regions of the earth.

In a general way, taking the earth's orbital movement around the sun and the earth's rotation on its axis into account, there should be only two seasons - summer and winter. In view of the tilt of the axis of rotation of the earth and the varying distances from the sun as the earth revolves around it, the seasons increase to four: the spring, the summer, the autumn and the winter. Even this classification does undergo modifications due to local conditions. In India, the long mountain ranges with different heights and orientations control the weather and hence the climate of different regions. Thus the climate conditions of different parts of the country, though could be grouped broadly, have different duration of periods that they last. The Himalayan ranges, the Kara Koram and Hindukush ranges, the Kasi-Garo and Arakkan ranges, the Vindhya-Satpura ranges and the ghats along the eastern and the western coastal belts play vital roles in determining and maintaining the

climatic conditions especially in the wind fields both at the ground and in the atmosphere aloft, in the temperature distribution and rainfall variability over the country. The obstacles in the path of general circulation will deflect the tracks of weather systems and block the passage of certain air masses. Due to orographic effect, the windward side of moist airflow receive more rainfall than the leeward side where the air has less moisture after raining it out on the windward side. Thus the climate on the leeward side is warmer and drier. Similarly, the climate over large oceanic areas are vastly different from that over land masses whose climate is distorted drastically due to the terrain formation and variations in the elevation.

Climatic seasons of India:

The seasons in India can be broadly grouped into four classes:

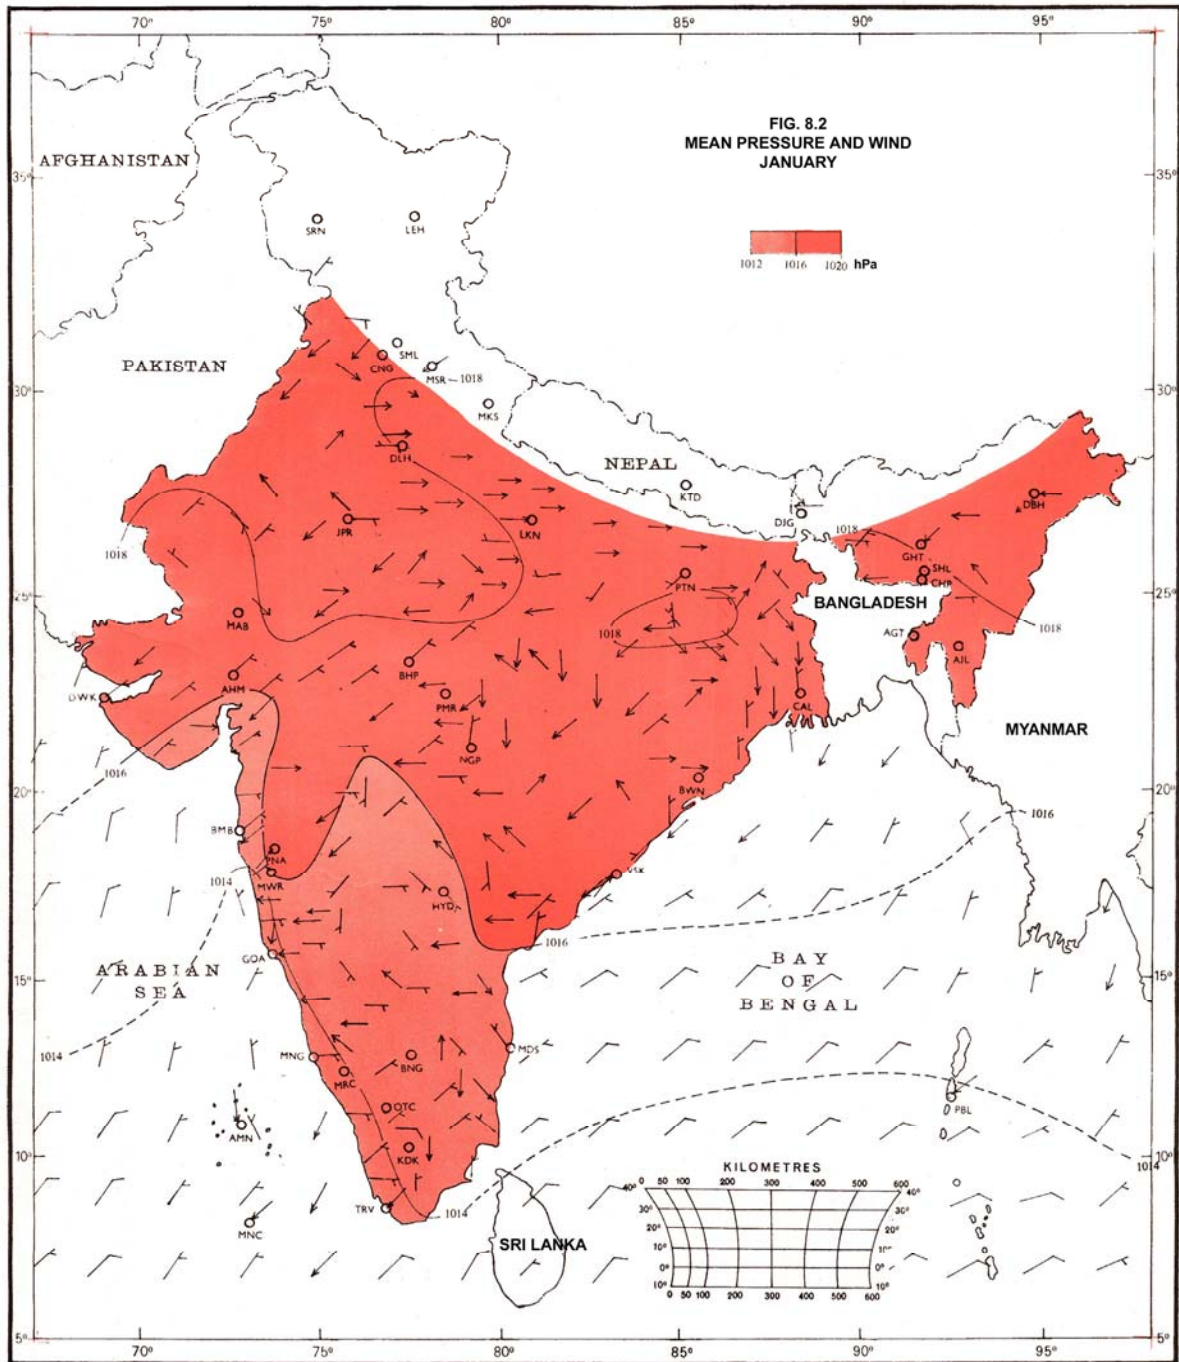

1. Winter season (December-February) some count it as January and February
2. Hot weather season or Pre-monsoon season (March to May)
3. Monsoon or Summer monsoon season (June to September)
4. Post monsoon season or transition period (October and November). Some include December in this.

Though the periods given cover broadly the seasons indicated, there are differences in the periods and durations at different places as dictated by the mountain ranges and the nearness to the marine environment.

Winter Season:

With the sun in the southern hemisphere, the land masses of northern India cool because of inadequate solar heating and radiational cooling. The equatorial low moves south of equator causing the subtropical high also to shift southwards and it lies over the central parts of north India. This results in dry atmosphere with clear skies, low humidity and low mean daily temperature with large diurnal range.

The pressure gradient (Fig. 8.2) from South to North is weak. A high pressure ridge runs along the West Coast and a trough of low extends off the Eastern Coasts. The diurnal variations in temperature can be of the order of 10°C or more except over the coastal regions of the peninsula. The semi-arid regions of western India have diurnal variations exceeding 15°C. The dry spell in the North is broken at intervals with the extra-tropical pressure systems moving from the West (with their initial formations over the Mediterranean area).

Source: Climatological Atlas of India

These systems normally are seen in the middle and lower troposphere and they are mostly frontogenesis. Over India they can be seen as low pressure area even over the surface.

As the low pressure area approaches, the pressure starts decreasing because the cold air of the place is replaced by the warm air of the warm front. The temperature starts increasing, as does the humidity. High clouds like cirrus appear in the hitherto clear skies and they start descending to form medium clouds (altostratus and altocumulus) to finally become low clouds (cumuli type). Occasionally even cumulonimbus (Cb – thunder clouds) clouds do form. From the time altostratus (As) clouds appear, light rain may occur.

The increasing trend in temperature ceases when the warm front is located over the place. No fresh cloud formation takes place and the rains may also reduce or stop. If any weather occurs, it is in the afternoons due to heat induced instability.

The warm front is suddenly taken over by the cold front which follows it. Large cumuli forms of clouds start appearing leading to thunderstorms. The wind direction changes from westerlies to north-westerlies and thunderstorms may even give rise to squally weather. The atmospheric pressure starts increasing. The skies clear and because of the availability of sufficient moisture, intense cold and fogs occur in the wake of the passage of the system.

The intense cold spell may continue for several days, giving rise to cold wave conditions causing serious hardships in the living conditions. When the normal minimum temperature is above 10°C, a persistent negative departure of 5°C to 6°C is termed a cold wave and if exceeds this limit, it is called severe cold wave. When the normal minimum temperature is less than 10°C, a departure of -3 to -4°C gives the cold wave condition. Normally the cold wave conditions start in NW India and spreads eastward as the cold front of the western disturbance moves eastwards.

These extra-tropical systems which move from West to East along about 30°N are called western disturbances (WD) in India. These give rains over Punjab, Haryana, Jammu and Kashmir and Himachal Pradesh. They also cause snowfall over the favourable locations in this region. The frequency of occurrence of the western disturbances is about:

November	December	January	February	March	April	May
2	4	6	7	5	5	3

As the winter gives place to the advent of the summer, the track moves southerly and comes down to Gujarat and Northwest Madhya Pradesh. On such occasions, the warm front may draw moisture from the Arabian Sea, giving rise to secondary or induced low and cause weather from Ahmedabad through Bhopal to West Bengal.

During the winter, the wind flow is generally westerlies. The wind speed builds up with height and reaches speeds of the order of 60-80 knots over the subcontinent. Above this, the wind speeds start reducing. The wind shear, the change in speed within small layers-vertical or horizontal is quite high. The westerlies move in the form of waves with ridges and troughs, with wavelengths from about 2000 km to more than 5000 km with varying amplitudes. The layer where the wind speed is higher than 60 knots is termed a jet stream and this overlies along 20°N latitude, normally at 200 hPa (more than 12 km high) level.

Southern points of the country experiences shallow easterly waves moving from East to West. This trade wind has a shallow depth (up to 3 km in height) controlled more by the prevailing westerlies above. The easterly waves are restricted to the Indian seas. They last for about 7-10 days. There is a convergent area at the rear part of the wave (after the ridge) with increasing wind speeds. As the wave approaches the eastern coasts of South India, it causes rain due to moisture picked up from the seas. The skies clear after the wave moves forward. Depending on the intensity of the low pressure developed, the degree of bad weather changes. The winter is mild over Tamil Nadu and Kerala because of these easterly waves and the nearness of the coasts.

Pre-monsoon or Hot weather period (March to May):

As the sun travels northwards from the equator, the equatorial low belt also moves up. The Indian seas, the Bay of Bengal and the Arabian Sea, which were not heated much by radiant energy from the sun during the winter, slowly react to the changes and continue to show lower temperature regime over the region. The solar heating of the waters does not increase the water temperature markedly due to the very large heat capacity of water bodies. On the contrary, the land masses are heated faster and reach high temperatures due to stronger solar irradiance at low angles of incidence.

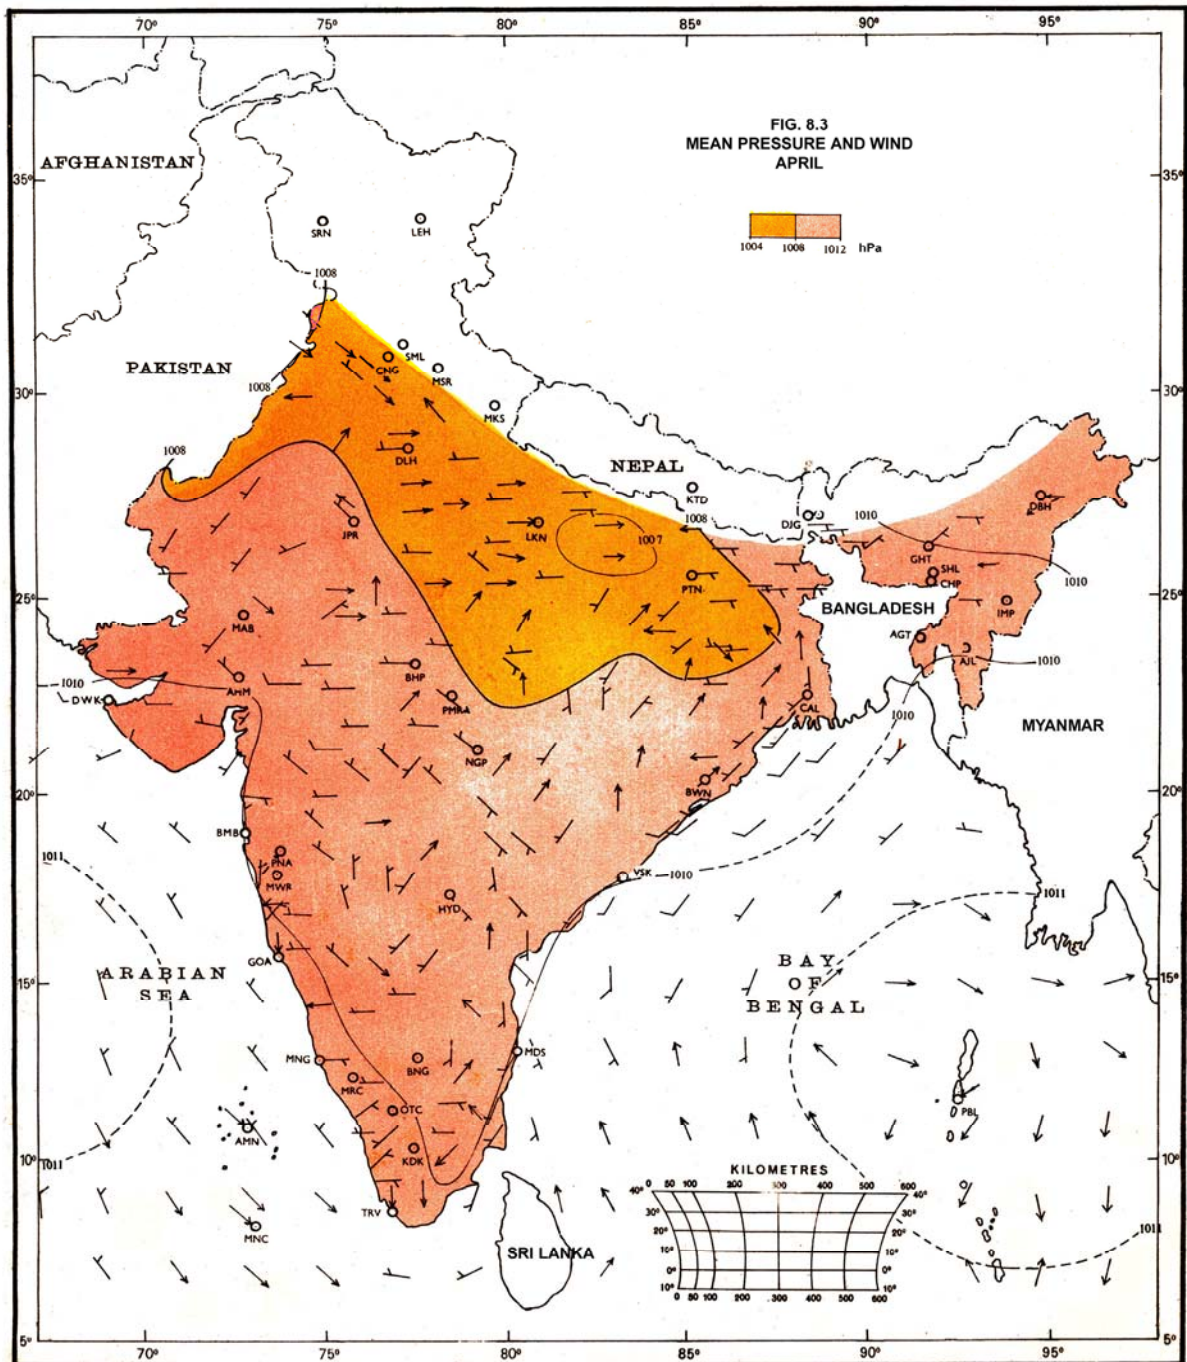

The pressure gradient which was from the South to North gets a reversal with higher pressure values in the South and lower pressures in the North. This is mainly due to the intense solar irradiances over the large land masses of the North. A weak low pressure cell appears over NW India and over Orissa. This Orissa low is a semi permanent feature which

occurs daily in afternoons. As a result, moisture incursion takes place and under favourable conditions, thunderstorms may develop. Over the peninsula, a trough of heat low forms along 78° meridian. When the air blows from the shallow highs of the seas, they bring in moisture. With the instability conditions already present due to heat lows, thunderstorms occur. The pressure distribution over India during April is depicted in Fig. 8.3.

The main weather conditions are:

- i) The western disturbances continue to be active but at lower latitudes than those in winter.
- ii) Depressions and cyclonic storms occur in the region
- iii) Heat lows occur over the Peninsula and over Orissa and adjoining area of Chattisgarh, Jharkhand and West Bengal
- iv) Strong instability conditions all over the country give rise to dust raising winds. In the northern parts, especially the NW India, sand storms and dust storms occur frequently. Thunderstorms, in many cases very severe ones, are frequent over the country.
- v) Heat wave conditions occur over the northern plains.

The eastward moving low pressure systems - western disturbances - occur over belts south of the areas affected during the winter. They draw moisture from Arabian Sea under favourable conditions and cause thunderstorm activities. As the systems move over to the eastern parts, they accentuate the semi permanent low. This causes large influx of moisture from the Bay. With intense irradiation from the sun, a series of thunderstorms develop. The thunderstorm thus developed is aided by the highly unstable atmospheric conditions. If the troughs of the upper air westerlies that prevail at this time overlies such an “unstable surface conditions”, the thunderstorm can be very severe one with towering cumulonimbus clouds giving rise to squalls of gale wind speeds followed by severe hailstorms and heavy rains. The squalls, caused by the downdrafts descending from the thunder clouds, will trigger other thunderstorms as the surface conditions are already under unstable conditions. Thus the thunderstorms travel from place to place generally from NW from Bihar and Jharkhand to the East or Southeast. Hence such thunderstorms are called Norwesters. An ideal condition for such development is to have a low level inversion, caused mostly by radiational cooling in the nights due to clear skies, and this inversion is broken by the strong solar heating just when the southeasterlies from the Bay provide the required moisture to cause super adiabatic lapse rates. The squalls, hailstorms and heavy rains cause extensive damages to small structures and standing crops.

Source: Climatological Atlas of India

Northers are thunderstorms generated over the convergence zone near the sub-Himalayan region in the East. The convergence is caused by the zone where the weak easterlies along the Himalayan ranges meet the southerly or southwesterly winds of Gangetic Bengal. The thunderstorms generated give rise to a series of secondary thunderstorms in the south of the area due to the northerly squalls from such thunderstorm. They normally reach the southern parts late in the evening as against the Norwesters which occur in the afternoons and evenings.

The northeasters take place in the morning hours normally over Assam regions. The westerlies of Gangetic West Bengal strike Khasi–Garo Hills. The inherent instability conditions of the season and the orographic rise of the westerly air cause thunderstorms. The resulting squall cools the surround air causing it to slide down the slopes to lift the warm air upwards to generate warm-cold fronts. This gives rise to northeastward movement of thunderstorms, giving rise to northeasters. Northers and northeasters are comparatively weaker systems.

Northwest India also has highly unstable conditions. The large cumuli type of clouds that occur do not have sufficient moisture content. The downdrafts that carry the rain droplets give rise to cool squally winds. The rain droplets more often evaporate below the cloud base itself. The cool squall brings down the air temperature but lifts up the dust and sand along with the warm air which it displaces. Depending on the strength of the squall, the amount of dust/sand raised varies, giving rise to dust storm/sand storm. The sand storm is restricted to the arid deserts of Rajasthan. North Gujarat, Punjab, Haryana and Western Uttar Pradesh are affected by the dust storms as the downdraft squalls trigger a series of thunderstorms. The dust raised may reach very high levels in the atmosphere. The dust content may be so heavy that the sun appears like a white disc casting no shadow. The dust particles take few days to settle down. These dust storms sometimes give rise to thunderstorms. They are locally called as “Andhis”.

The inherent instability conditions of the warm surface coupled with cloudless skies cause intense heating. The hot air flow from the NW India, aided by the prevailing westerly winds, moves eastwards giving rise to higher temperature regime for few days. When this condition persists for extended period with a departure of 3°C or more, heat wave conditions are said to exist. The plains of North India and adjoining Gujarat and Maharashtra experience this type of heat wave. Southern peninsula experiences thunderstorms due to the N-S heat lows over the Plateau and northwesterly and southwesterly winds along the coasts giving rise to zones of discontinuity over Karnataka. A diurnal shift of the discontinuity towards the Bay occurs due to the warmer sea surface over the Bay during the

night. They normally do not shift westward because of cooler temperature of the Arabian Sea water surface. As the solar irradiation increases from the morning hours, the land becomes warmer and the zone of discontinuity shifts to mid peninsula. By this time the sea breeze sets in bringing in more moisture giving rise to thunderstorm activity. On the West Coasts the thunderstorm activity is stronger due to the added orography. These thunderstorm activities start from March itself and the frequency of occurrence and their strength increase as the season advances into May. On an average about 12-15 thunderstorm days occur over the West Coasts.

This is also the period of occurrence of tornadoes. Tornadoes are extremely severe form of thunderstorms. A tornado is a vortex field, in a thundercloud, with small horizontal extent of severe intensity. This extends downward from the base of a thundercloud in the form of a funnel shaped cloud. The diameter of such a funnel may vary from few metres to several hundred metres. Because of the intense vortex motion within, the winds near the core may exceed even 400 kmh^{-1} . At the approach of a tornado, a continuous rumbling sound starts. This may increase to a roaring sound. Following its passage, a hot and suffocating air is left behind. Large sized hailstones are in preponderance rather than the rain droplets. The difference in the pressure between the centre of the funnel and the outside air can be as high as 100 hPa. The winds outside are also strong and cyclonic and converge to the core of the funnel, forcing a very strong upward motion of the air. In the process, whatever loose and light articles that happen to lie within the funnel are sucked up and carried along as the thundercloud moves, only to be dropped somewhere away from their locations. The tornadoes move at a velocity of $100\text{-}150 \text{ kmh}^{-1}$. Thus tornadoes cause heavy damages to most of the articles that may be within the zone of their travel. The life of a tornado is short one from few minutes to an hour. A highly favourable condition for this is to have large vertical shear in the middle layers and high humidity in the lower levels. The Indian region is not frequently subjected to tornadoes. They occur normally in Assam and adjoining states including West Bengal. More than 70 per cent of the tornadoes that have been reported in India are from this NE India. The remaining ones occur in different parts from Punjab to Bihar.

Tropical Cylonic Storm during the pre-monsoon period:

The warmer sea surface temperature heated by the solar irradiance provides a potential state for the development of low pressure areas in the latitude belt of Bay of Bengal $10\text{-}15^\circ \text{ N}$. When a trough zone of an upper air wave overlies the belt or a low pressure system enters the Bay from China seas, a low pressure cell forms. This gets accentuated when an upper air trough of an easterly wave lies above. The pressure starts falling as the

surface warm and moist air is sucked by the divergence of air in the upper layers that exists. When the trough of a westerly wave, that exists north of the subtropical high pressure ridge, arrives at the same meridian over which the trough of an easterly wave lies, the divergence in the upper air over the low pressure area deepens leading to the formation of depression, deep depression and cyclonic storm. The gradation of the low pressure system depends on the departure of the atmospheric pressure with reference to the normal pressure value. The movement of the system depends to a large extent on the relative positions of troughs of the easterly and westerly waves and their speed of movement across the disturbed area.

During the pre-monsoon period such systems have their origin in the latitude belt 10-15° N in the Bay region. The systems when fully developed may have a surface diameter of about 600 km. Near the central part of a fully developed storm, a calm area (the eye) forms and covers an area of 40-50km diameter. Within this eye, the winds are calm and the clouds, if they exist, are not rain bearing type and hence no rainfall occurs. Just outside the eye, walls of rain bearing thunderclouds exist towering up to even beyond 12 km. This is an area where gale winds having speeds of the order of 60-100 kmh⁻¹ occur, accompanied by lightning, thunder and torrential rains. The wind speed decreases as we move away from the eye and the pressure values also decrease outward. Normally these systems move in a westerly/north westerly direction. As they move, they generally gain more moisture and become more severe. As the storm crosses the coastal line, it causes large amount of destruction to property and crops because of the winds of hurricane speeds and torrential rains. A major hazard is due to the storm surges when the sea water of about 3-4m high enters inland and inundates vast areas along the coast. However this does not occur with every storm. As the eye crosses a location, the winds again pick up speed and blow from opposite direction. The storm starts weakening over the land due to the absence of sufficient water vapour over land masses and due to the draining of water content in the clouds following the torrential rains.

A storm may weaken even over the seas after the trough in the upper air passes past the surface low or a cold air fills up the upper layers. Depending on the relative positions and speed of the upper air waves, the westward movement of the system may be retarded and the whole system may turn northward or northeastward.

After crossing the coast, the storm may decay rapidly into low pressure area giving rise to extensive rains before the low pressure cell is filled by the descending air from above. It is also possible that the low pressure area moves westward from Orissa coast and as it nears the western half of the peninsula and picks up fresh moisture from the Arabian Sea to cause heavy precipitation in its path.

During the pre-monsoon period, about 70 per cent of the storms do not hit the Indian coasts. The frequency of occurrence of the storm is more in May during which period the probability of affecting the Indian coasts is more. Storm occurs very rarely over the Arabian Sea and they, if occur, generally move away towards the Arabian coasts. Only those which originate very close to the Konkan coasts may cross the North Maharashtra or Saurashtra coasts. Table 8.1 below gives the number of cyclonic storms that originated in the Indian seas (Tracks of storms and depression (1971-1990) – India Meteorological Department).

Table 8.1

	J	F	M	A	M	J	Jy	A	S	O	N	D	Total
Bay of Bengal	1 (1)	0 (0)	0 (0)	2 (2)	11 (9)	3 (1)	3 (0)	4 (2)	7 (4)	16 (8)	27 (20)	8 (5)	82 (52)
Arabian Sea	0 (0)	0 (0)	0 (0)	1 (0)	4 (2)	3 (2)	0 (0)	0 (0)	2 (2)	5 (5)	1 (1)	1 (1)	17 (13)

The number of storms which reached “severe” intensity is given in brackets.

Monsoon Period (June-September):

This is also called South-West monsoon or summer monsoon. This is the season in which major parts of the country receive most (if not the entire) of its annual rainfall. However, the season is not uniformly rainy. Monsoon rainfall may be significantly different from year to year; even during successive monsoon seasons. The primary driving force is the seasonal imbalance in temperatures between land and sea. The monsoons are the largest perturbations in the global zonal flow. The sun’s path is located during this season mostly over latitudes north of 15°N and causes intense heating over the land areas. As a result, a semi-permanent seasonal low pressure develops over NW India. The trough of low which normally lies over the equatorial region, also shifts to the North and merges with the low pressure cell of NW India and the axis of trough of low pressure runs from Western Rajasthan to West Bengal. Along with this, the trade winds which were from south-east in the southern hemisphere turn to the right after crossing the equator and gradually becomes south-westerlies as they travel northward. The West Rajasthan low pressure is normally centred around 994 hPa and the pressure values gradually increase eastward and southward to a value of about 1008 hPa. Such a strong pressure gradient naturally increases the wind flow and affects the weather of India.

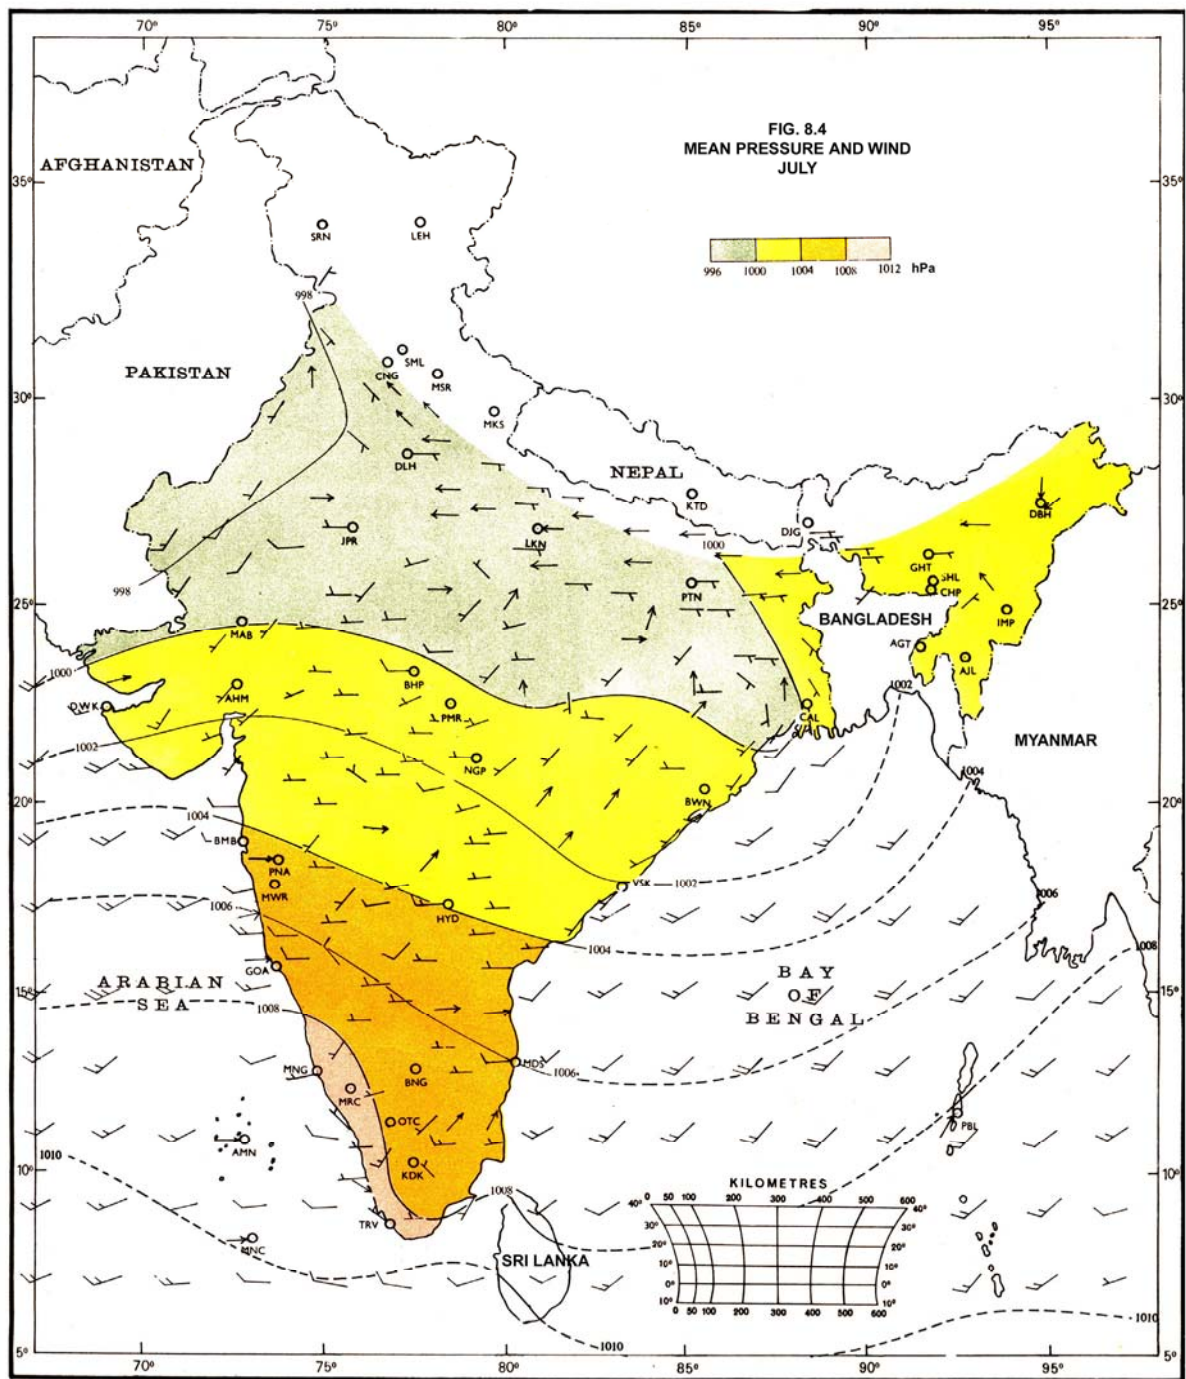

As the summer advances the westerly jet stream and the subtropical ridge (high) move northwards to lie north of 30°N. This enables the lower tropospheric easterly waves to become prominent and increase in its strength and in height over the region south of 15°N.

Onset of Monsoon:

A change in the wind direction from the normal northwesterlies to southwesterlies occurs. A perturbation in easterly waves causes a midtropospheric trough, which in the wake of its divergence sector over the warm and humid sea surface, generates a low pressure area over the south Bay and SE Arabian Sea. By this time, the increased wind speeds in the higher levels of easterlies culminate in the formation of a tropical easterly jet stream with a core speed of about 60-70 knots and it generally lies over 10°N latitude. When a second easterly trough overtakes the surface low pressure area, extensive heavy rains occur over South Kerala coasts. A depression in south-central Bay or in the SE Arabian Sea is also a very favourable condition for the monsoon to set in. Sustained heavy rainfall over coastal Kerala heralds the monsoon. The skies become overcast and winds are southwesterly extending to about 3 km in height. The southwesterly winds from Indian Ocean fork into two branches; one hits the West Coasts and the other crosses the Bay of Bengal and strikes the coasts of West Bengal, Bangladesh and Myanmar.

The monsoon sets in first over Andmans by mid May itself and over Kerala coasts by about June 1. The monsoon advances rapidly over the peninsula and reaches Gujarat by June 15. This branch brings rainfall over the entire peninsula (outside Tamilnadu) and the coasts of North Andhra Pradesh and Central India. The Bay branch reaches the NE states by June 5. The tall mountain barriers of NE India and the Himalayas divert the southerly winds eastward. The winds are, therefore, from East or South-East over the Gangetic Plains, north of the seasonal trough of low extending from Rajasthan to Bengal coasts. This trough effectively becomes the well developed equatorial trough and is called the axis of monsoon trough (AMT). The winds are southwesterly, south of this trough and easterlies to its north. The meeting of the two wind fields give rise to wide spread thunderstorm activity over the area. Monsoon covers Uttar Pradesh and other NW India by July 1 and it reaches West Rajasthan by July 15. The pressure distribution in July is depicted in **Fig. 8.4**.

The latitudinal position of AMT which is roughly from Ganganagar in Rajasthan to Kolkata in West Bengal under normal condition changes from day to day depending on the relative strengths of wind circulation over different parts of the country. The orographic effect is active only when the winds strike the mountain barriers at near normal incidence

Source: Climatological Atlas of India

and this causes good rains. If the winds, however, happen to be southerly parallel to the mountains, the rains will decrease. An offshore trough along the west coasts, or a low-pressure system in the Bay of Bengal reactivates the rainfall activity. When the southwesterlies are weak occasionally, they are reflected by the Western Ghats causing a small vortex field over a localized small area. The resultant vorticity circulation generates large instability of air over the Konkan Coasts and the huge ascending columns of air give rise to localised heavy rainfall (even exceeding 30 cm of rain in 24 hours).

A major cause for good rainfall over large parts of interior Central India is the formation of low pressure area over the northern parts (head) of Bay of Bengal and its subsequent strengthening into depression. The inherent instability over the Bay or the movement of a low pressure system from China Seas strengthens into a low pressure area over the head Bay when a westward moving easterly wave affects the region. Large amount of converging winds over the southwestern warm sector of the system feed to the deepening of the low pressure into depression and then to deep depression. The moist and strong southwesterly winds are drawn into this area, causing heavy rains all along the West Coasts and interior Karnataka and Maharashtra. There is widespread rain over the coasts of North Andhra Pradesh, Orissa and West Bengal. Once the depression crosses the coasts, the depression weakens into a low pressure area. Good rainfall occurs over Jharkhand, Chattisgarh, Madhya Pradesh and Vidarbha (East Maharashtra) regions in its wake. If the westward or west northwestward movement persists, the low-pressure area may again strengthen by drawing copious moisture from the Arabian Sea and cause extensive heavy rainfall over North Maharashtra, Gujarat, East Rajasthan and West Madhya Pradesh. In most of the cases the extensive rainfall ceases when this system merges with the seasonal low over West Rajasthan. Normally the life cycle of such a system is 4-5 days. These monsoon depressions do not normally intensify into cyclonic storms. Most of the depressions occur in July and August. As the season advances into second half of August, the depressions generally move NW after crossing the Coasts and turn northward to give extensive rains over West Uttar Pradesh, Haryana, Punjab and West Rajasthan.

Break in Monsoon:

During the monsoons, Jammu and Kashmir is not affected as the subtropical ridge lies over these latitudes and the subtropical jet stream north of it. This causes good solar heating over the high pressure areas of Tibet. This is said to maintain the easterly waves as an outflow from this high pressure area. When an eastward moving extra-tropical disturbance or the associated westerly trough passes over the region, it pulls up the AMT close to the foot of the Himalayas. This causes a strong decrease in the rainfall regime over

the Peninsula and Central India. The meeting of the weak south-westerlies and strong and narrow easterlies cause heavy rains in the northern areas adjoining the Himalayas. During this period, a break in monsoon is said to occur. The main feature of this break in monsoon is the heavy rainfall along the foot hills of Himalayas and low rainfall distribution in the rest of the country. The tropical easterly jet stream which was positioned over 10° N moves northward to lie over $15-18^{\circ}$ N belt and get strengthened with core winds of about 120 knots. The Tibetan high becomes active due to the strong thunderstorm at the Himalayas and the associated excess release of latent heat energy.

Revival of the monsoon:

The break in monsoon generally lasts 4-6 days. The revival of monsoon occurs when the AMT is brought back to its normal position. This can happen when (i) the extra-tropical disturbance which pulled AMT northward moves away, (ii) the upper air easterly trough is favourably positioned with sufficient strength and (iii) a low pressure system in the form of low pressure area or a depression develops at the Head Bay. The monsoon is active when the AMT extends into the Head Bay area giving rise to a very good rainfall over extensive regions. It becomes vigorous when heavy rainfall occurs over selected and favourable areas as in the case of a monsoon depression.

Rains in Tamil Nadu adjoining Andhra Pradesh:

Situated in the rain shadow regions of the Western Ghats, the moist south-westerly winds and rain bearing clouds are drained off their moisture content over the western sides and only a dry spell results in the eastern regions of the Ghats. The afternoon cumuli clouds develop and with favourable moist sea breeze incursion, thunderstorms occur over the area and give rise to thundershowers. During the break monsoon period, low pressure waves move in the south Bay westward. The southerly or southeasterly winds draw moist air and cause thundershowers over the southern Coastal Andhra Pradesh and Tamil Nadu Coasts and the adjoining areas.

Withdrawal of Monsoon:

The sun starts moving southward by July and it is to the south of the equator by September. The rate of heating by irradiation starts decreasing causing the cooling of the surface. The seasonal low pressure areas get filled up drawing in cold continental air. The sea waters which were heated up earlier, however, remain warm compared to the temperatures of the land masses. The rise in the pressure is more in northern India. The

northern Bay also starts cooling very gradually. The wind flow which were from SW or SE, changes to be from N or NE. This causes the pushing the equatorial trough to South by 1st September. By 15th September, the monsoon circulation generally ceases from most part of the country except the South Bay and Kerala. Drawing in of continental dry westerlies accompanied by the reversal of pressure gradient from North to South indicates the withdrawal of monsoon.

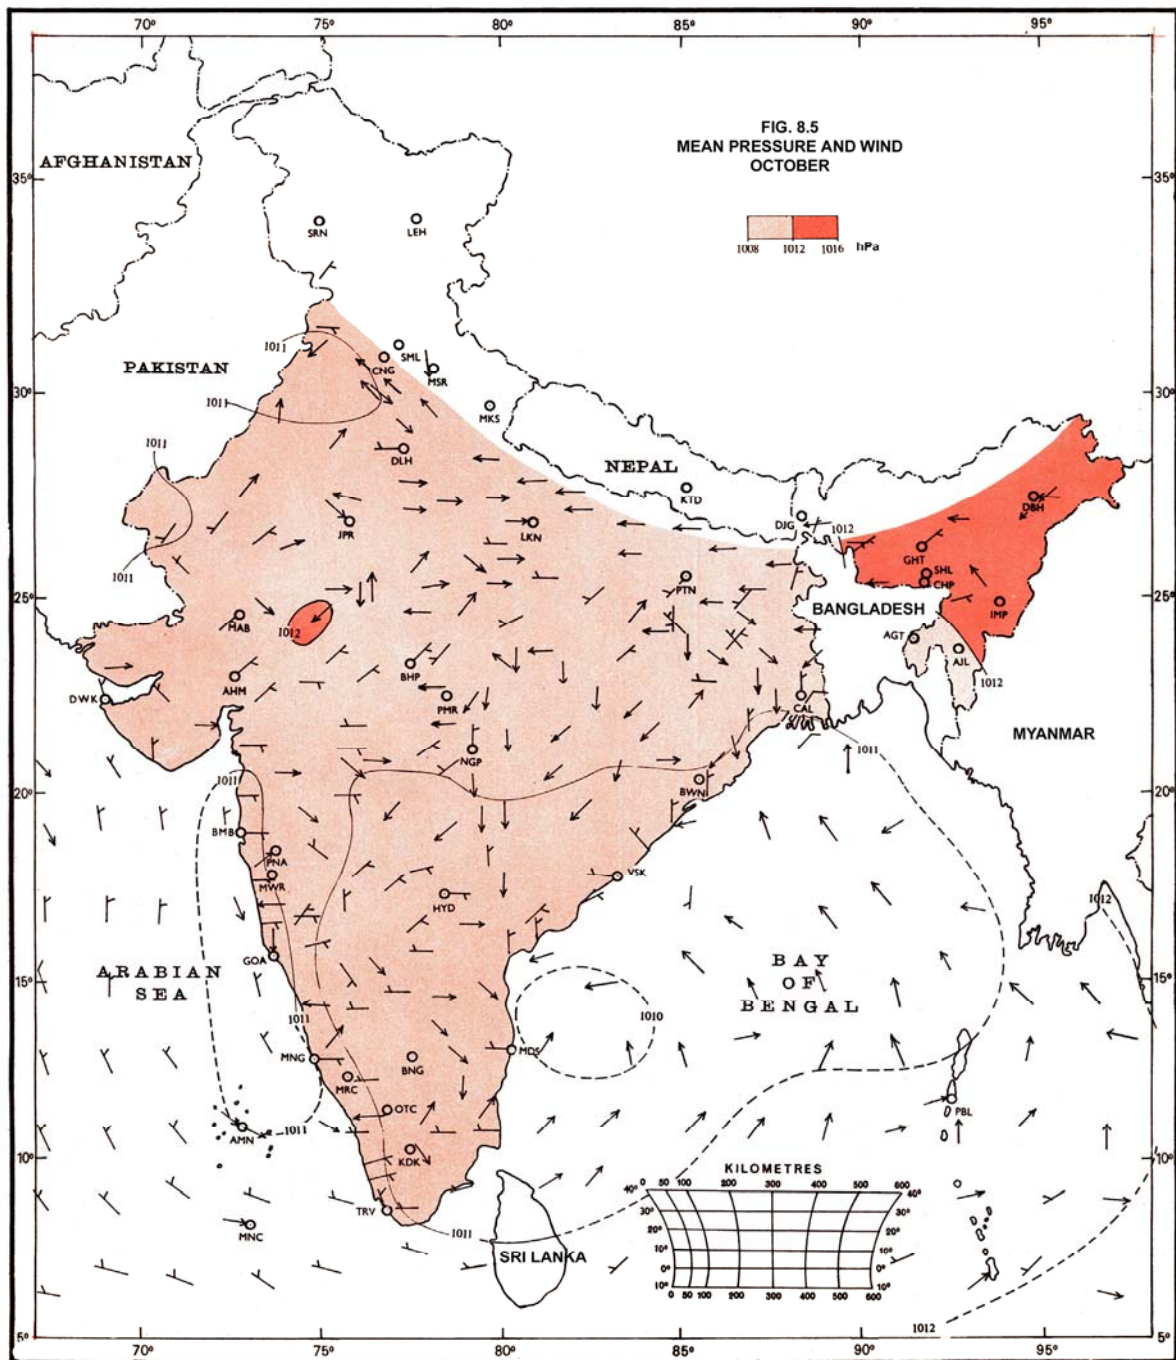

Inter-annual Variability:

The monsoon activity is not of uniform type. The season is not uniformly rainy even at a given location. Similarly, monsoon activity can vary from year to year significantly with regard to total precipitation, spatial distribution or even uniform dispersal throughout the season. Over the years there are several occasions when the rainfall was quite low. In most of such occasions, periods of prolonged break, long delay in the onset of the monsoons or early withdrawal of the monsoon from the country are noticed. Though the monsoon effect is quite high in our country, it has a link with the sea surface temperatures off the Peru Coast. The warming by December for a short-period in that region may extend and spread over Central Pacific Oceans. Under such circumstances, it (called El-Nino) causes weakening of monsoon activity resulting in a large rainfall deficit from the normal. This results in the incidence of drought over the areas of deficit rainfall.

Post Monsoon period (Transition Period) (October and November):

As the sun moves south of Equator, the land areas of the north cool rapidly. The equatorial trough which was the axis of the monsoon trough during the monsoon season also moves southward. This causes the southwesterly winds of the monsoon to cease blowing over most parts of the country. The wind field to the north of the equatorial trough reverts to northeasterly trades. These winds when they travel over Bay of Bengal and reach the East Coast of southern Peninsula cause rains along the coastal regions of South Andhra Pradesh and Tamil Nadu.

During this period, the subtropical ridge (high pressure) which was located near 30°N during the monsoon also moves down southward. The westerly subtropical jet stream also makes its southward movement and is located south of 30°N by November. The pressure distribution during October is given in **Fig. 8.5**.

Source: Climatological Atlas of India

The northeasterly winds from Bay of Bengal appear, as the south-westerlies of the monsoon move to extreme South and thus establishing the North-East (NE) monsoon over South Andhra Pradesh, Telengana, Interior Karnataka , South Kerala and Tamil Nadu. The tropical easterly jet stream which was a very prominent feature during the monsoon completely disintegrates as the SW monsoon withdraws. A low pressure area establishes itself over the central and south Bay by October. It shifts to south Bay in November and further to south by December. No such low pressure area occurs in Arabian Sea. These low pressure areas move westward, in many cases (without any development) to form depressions and they affect the weather over the southern Peninsula. About 2 or 3 such low pressure areas occur during October and November, mostly formed in situ, perhaps due to sustained warmer sea surfaces during the season.

The seasonal East-West trough is across the south Peninsula during October and it moves more to the extreme southern parts. In December except for the coastal Tamil Nadu, the winds are mostly of land origin. Their activity is interrelated with the seasonal low pressure areas.

When the divergence portion of the easterly wave overlies the low pressure area, the pressure starts reducing due to the suction of the converging air at the sea surface and a depression forms over the area. When an eastward trough lies in conjunction, to the north of the subtropical ridge, large-scale removal of air occurs and the depression passes through stages of deep depression, cyclonic storm and some times severe cyclonic storm.

Table 8.2 shows the depressions and cyclonic storm that formed during this season during 86 year period from 1877-1972.

Table 8.2

	Month	Depressions		Cyclonic storms		Severe Cyclonic storms		Total
		1 st fortnight	2 nd fortnight	1 st fortnight	2 nd fortnight	1 st fortnight	2 nd fortnight	
Bay Area	Oct.	41	38	19	23	11	20	152
	Nov.	20	17	28	13	25	18	121
	Dec.	14	10	11	11	12	5	63
Arabian Sea	Oct.	5	4	2	9	3	3	26
	Nov.	4	3	2	2	7	3	21
	Dec.	1	-	3	-	-	1	5

The number of storms is more in November, whereas October nurses more depressions. More than 60 per cent of these storms strike the Indian coast. The entire coastal regions of Andhra Pradesh and Tamil Nadu are susceptible to these storms in October. The North Tamil Nadu coasts are prone to be affected more in November and December. Sometimes these storms cross the narrower continental mass of the south Peninsula and intensify again in the Arabian Sea, affecting the Western Coasts. Most of such storms move northward and affect North Maharashtra- Gujarat coasts. The heavy rainfall during this season is generally accompanied by thunder and lightning. Generally a rainfall spell lasts 3-4 days.

The extra-tropical disturbances that travel eastwards in the westerlies north of the subtropical ridge generally do not enter the Indian region in October. They progressively affect the extreme northern parts by November-December and may cause rains over western Himalayas and adjoining areas.

Rainfall Distribution:

India being a large country the rainfall distribution varies widely from almost negligible rains in the arid regions to heaviest rainfall areas. The rainfall is associated chiefly with the following phenomena.

- (i) Thunderstorms
- (ii) Extra-tropical disturbances (Western disturbances)
- (iii) Tropical depressions and cyclonic storms
- (iv) The monsoon

Thunderstorms:

A prerequisite for a thunderstorm rain is the potential atmospheric instability and moisture availability. The atmospheric instability requires sufficient surface heating by solar irradiance and hence the occurrence of thunderstorm during the winter is minimum. However, the lifting up of moist air can also be effected by the squally downdrafts from a thunderstorm or by the incursion of dry air as in case of the rear of a western disturbance. Normally the intensity of rainfall at the beginning of a thundershower is for few minutes only and decreases gradually after the peak and the rain lasts longer.

Extra-Tropical Disturbances (ETD) or Western Disturbances (WD):

They are mainly active in the northern parts of India and especially during the winter and premonsoon months. They are front types. The warm front gives light but continuous rains and the cold front causes severe thunderstorm with heavy showers. The extreme northern parts around 30°N experience these rains during winter and in June. This type of rains occurs at much lower latitudes even as South as 20°N during April and May.

Tropical Depression and Cyclonic Storms:

The rains due to these disturbed conditions can be very widespread and very heavy too. The rainfall is normally very heavy when the pressure system moves slowly. The maximum amount of rainfall is over the coastal region when the system is concentrated over the seas. As the system weakens on crossing the Coasts, they cause widespread rains as a well marked low pressure area though not very heavy as it does over the Coasts before or at the time of crossing the Coasts.

Monsoons:

Southwest monsoon is the main cause for the country's rainfall amount and distribution. The rain is not a daily occurrence. It occurs in spells of about 5-7 days. These spells mark the active monsoon periods giving good rainfall in the plains, the West Coasts and NE India. Southeast peninsular India and the areas at the foothills of Himalayas receive less rain. When the monsoon weakens or when there is a break in monsoon, the Sub-Himalayan regions get copious rains and the rainfall also increases over SE Peninsula.

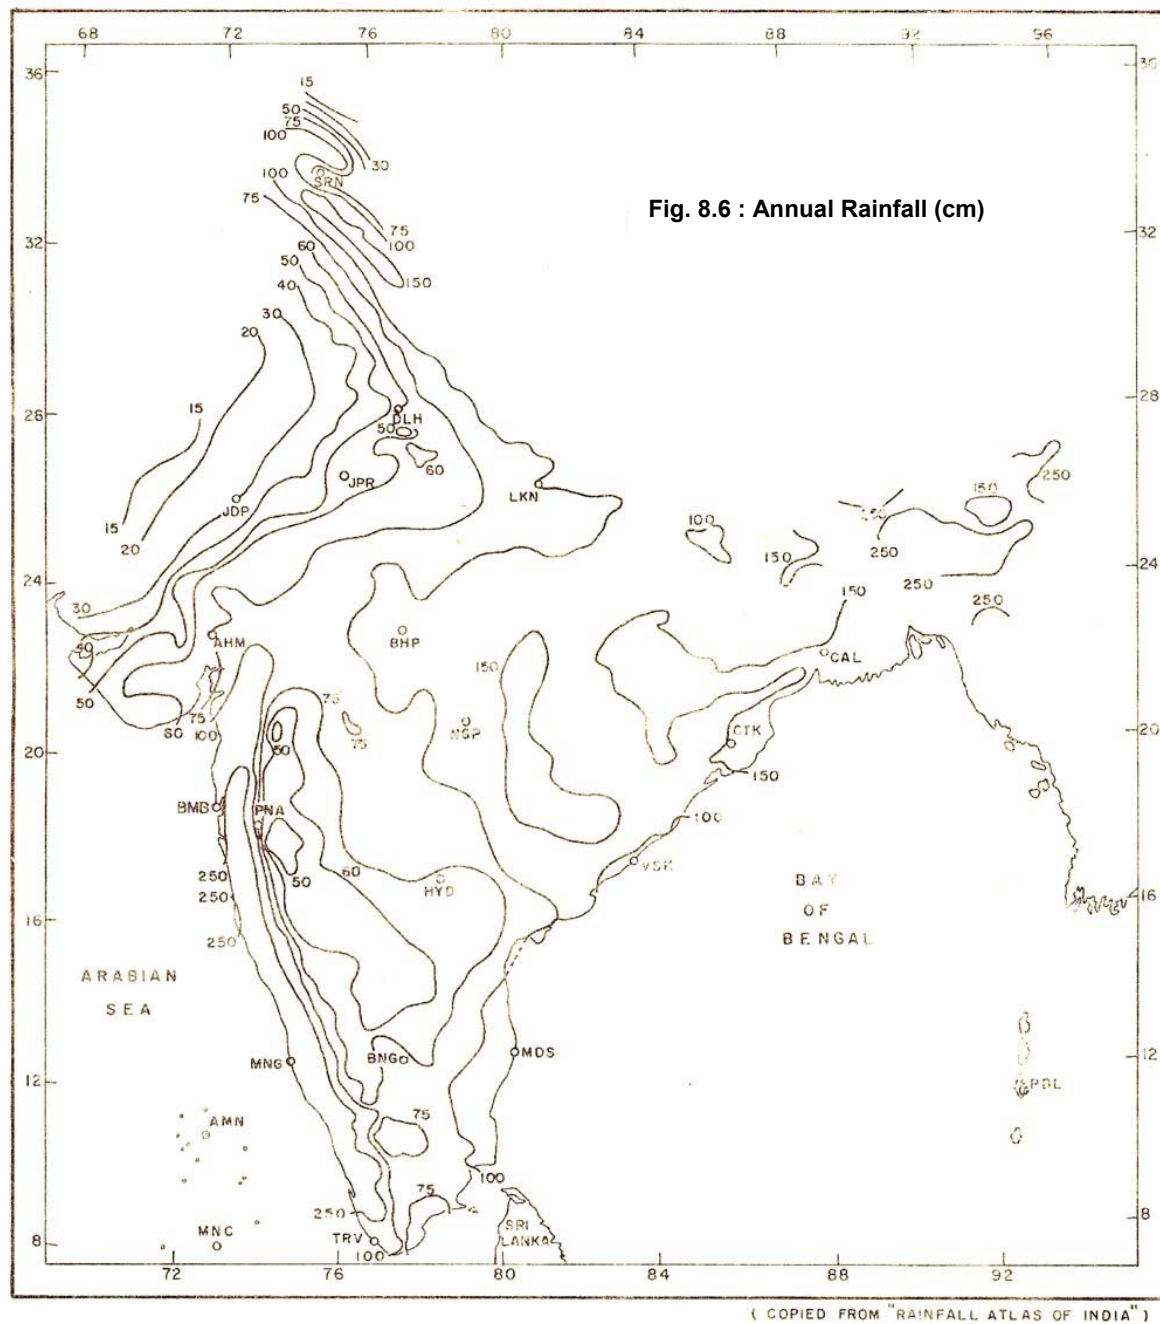

When the SW monsoon withdraws, the NE monsoon sets in over SE Peninsula and Kerala and gives good rains, though not of the same level as that of SW monsoon.

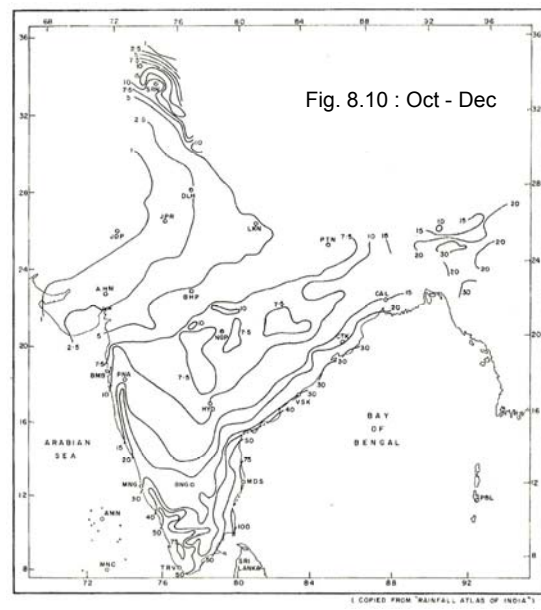

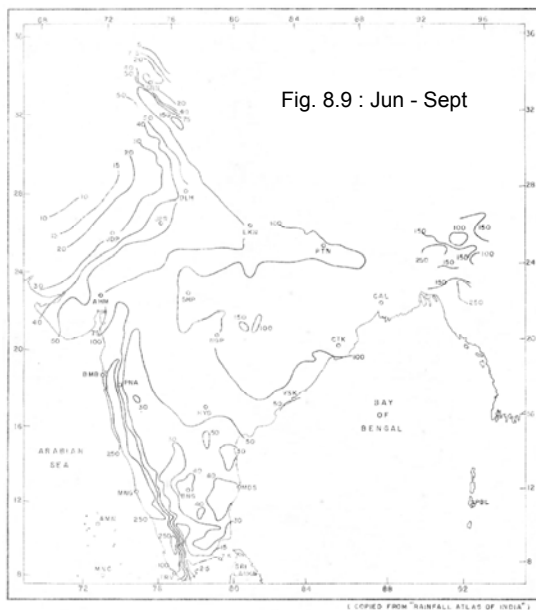

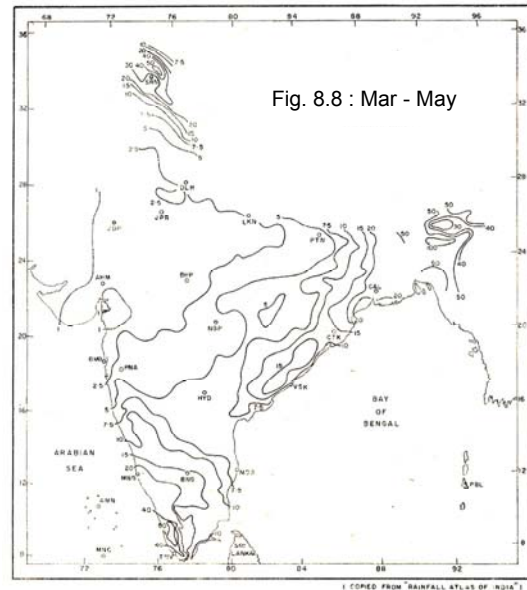

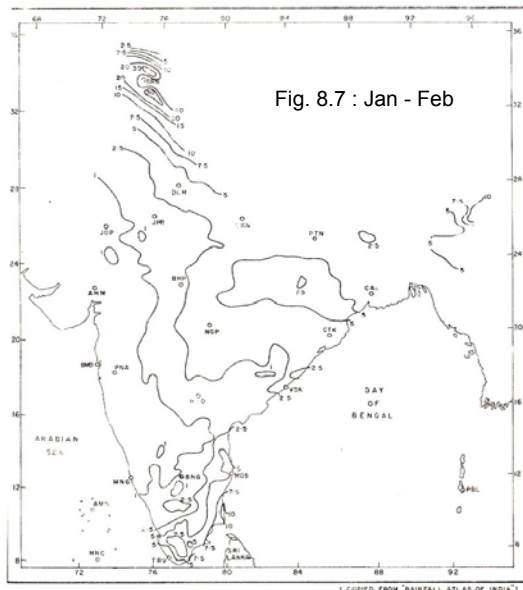

The average distributions of rainfall during the whole year and during the four seasons are depicted in Fig. 8.6 to 8.10.

Occurrence of Thunderstorms:

Thunderstorms are local phenomena causing intense local rainfall. These arise when large-scale convective activity is caused. The clouds associated are towering cumulus and cumulonimbus types having violent updrafts, downdrafts, thunder and lightning. Though a thunderstorm may last 5-6 hours, a shower from it will be generally less, about 2 hours.

Thunderstorm activity is low during winter season. It is confined mainly to northern parts of India, mostly associated with the extra-tropical disturbances. As the season advances into February, the frequency of occurrence increases especially in the eastern and northern India. Very few thunderstorms occur over extreme southern Peninsula (South Kerala and West Tamil Nadu).

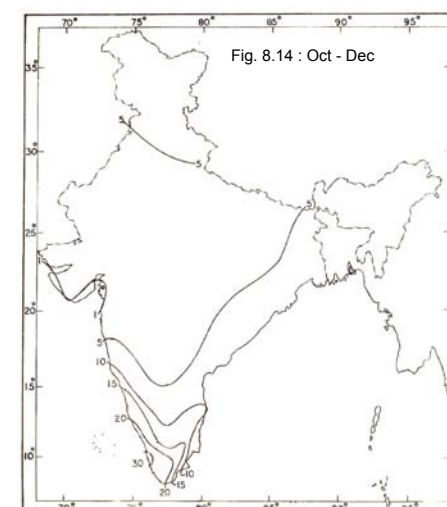

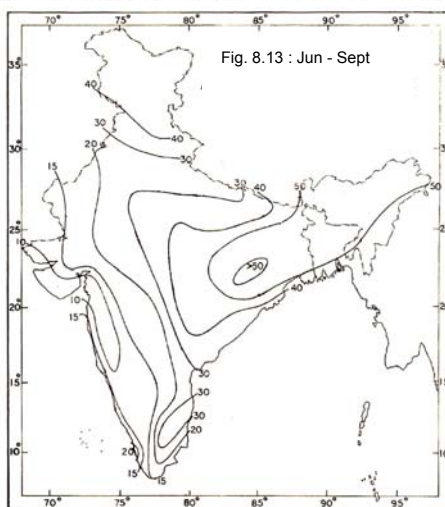

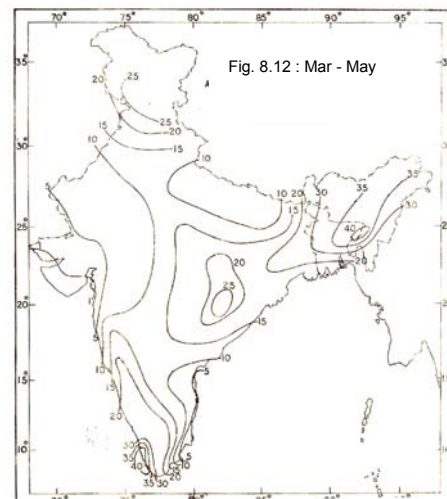

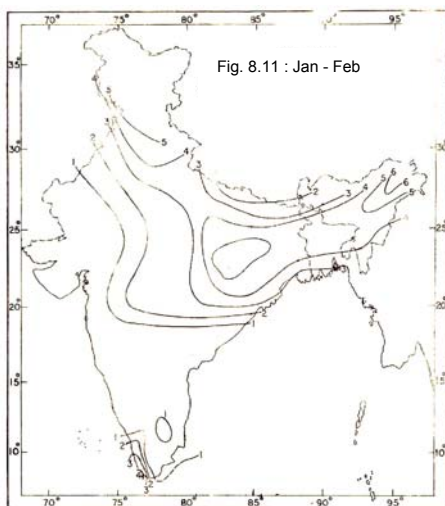

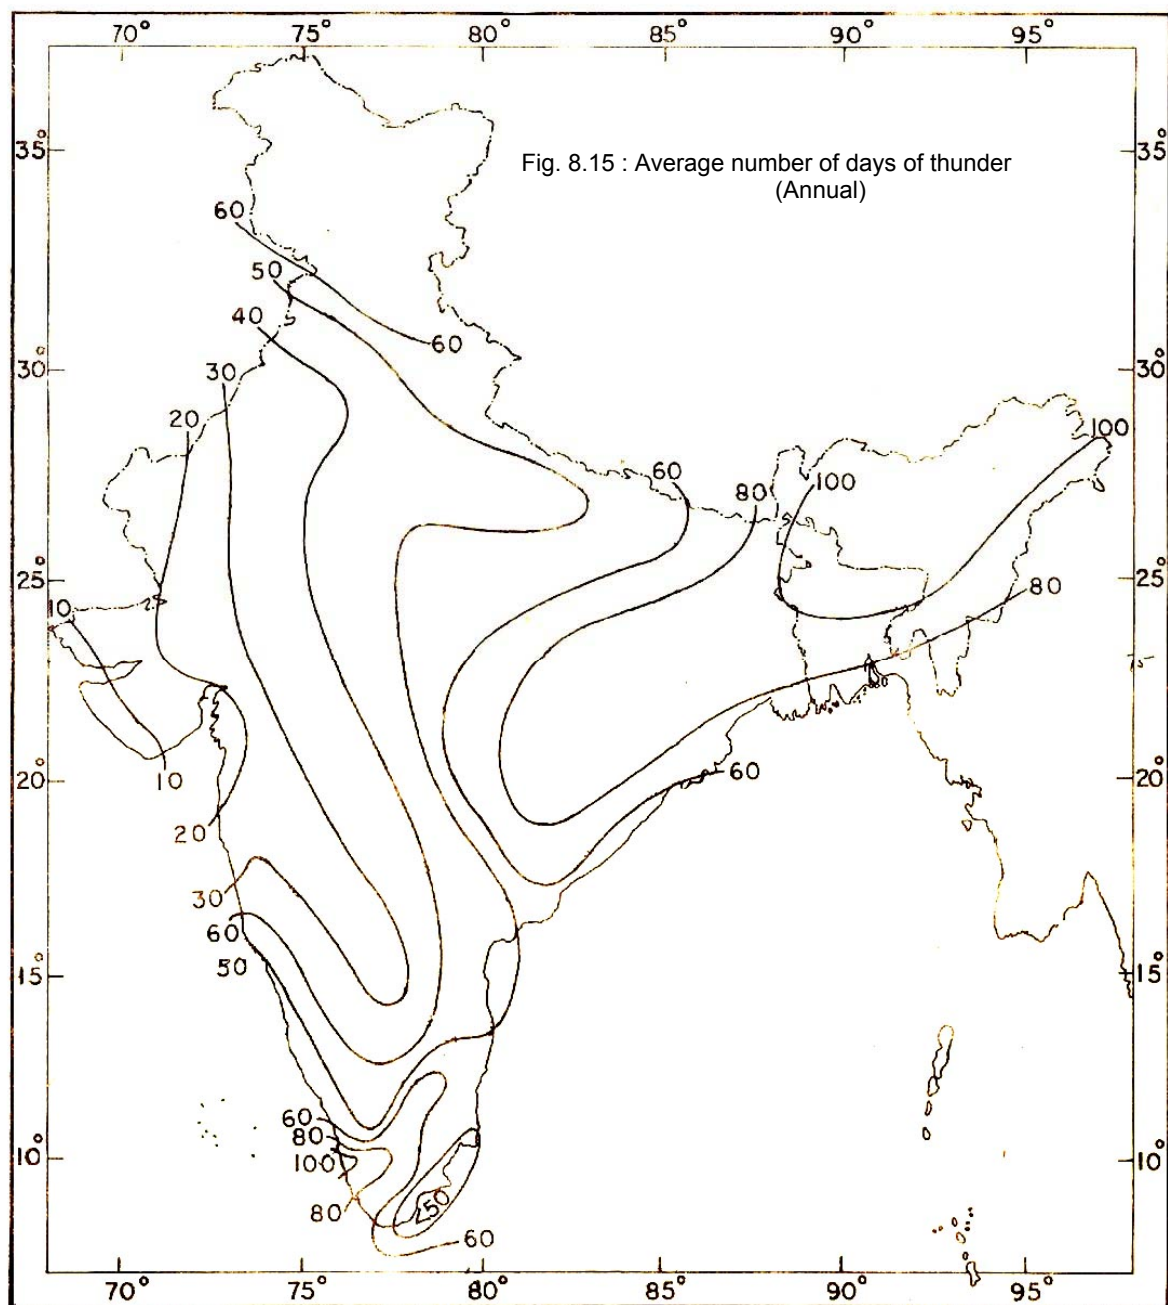

Seasonal Rainfall (cm) over India

The pre-monsoon hot weather period has intense convective activity caused by solar heating and large lapse rate (rate of decrease in temperature with height). Two zones of maximum activity are experienced, one over NE India and the other over Kerala. In April, the frequency of occurrence increases to 12-14 days. In contrast the western regions of Gujarat have little activity.

The thunderstorms for more than 16 days even in June occur over Central India and extreme North India. During the monsoons, the western India has no or little of thunderstorms. By September, the maximum activity is over the eastern India. By October, with NE monsoon becoming active, the thunderstorm region shifts to SE India (Tamil Nadu, Kerala and Coastal Andhra Pradesh). By December there is minimum thunderstorm activity over India. Figures 8.11 to 8.15 (Sc. Rep. 153) show the thunderstorms during different periods of the year and for the year.

Average number of days of thunder

A **tornado** is concentrated revolving storm with a near vertical axis with strong updraft of high rotational velocity and quite a low pressure in the centre as compared to the atmospheric pressure outside. They originate in very severe thunderstorms and is visible as a narrow funnel below the cloud base. When the tip of the funnel is close to the earth's surface, it causes enormous destruction by lifting and twisting all objects in its path. The phenomenon is rare in India. It occurs mainly (more than 70 per cent) in the East and NE India.

Hail is precipitation in the form of solid ice. They occur when intense thunderstorm activity occurs. They occur only when cumulonimbus clouds exist. The ice particles that form above the freezing level are tossed up and down by the strong winds and they coalesce into small stone-type ice blocks. They may be thrown out by the down drafts at the mature stage of the thunderstorm. The thunderclouds will still contain a large number of the hailstones.

Hailstorms are common in winter and the pre-monsoon months. Monsoon period is free from hailstorms. Hailstorms are more in the winter months over NW India, Uttar Pradesh and Madhya Pradesh. They are more prevalent over NE, Peninsula, Vidarbha and adjoining MP during the pre-monsoon season. The number of hailstorms is one or two orders of magnitude less than the number of thunderstorms.

Heat waves:

During the pre-monsoon period and June, the normal temperatures are generally high over the Indian subcontinent. If the hot spell is over extended days, heat wave condition is said to exist. When normal maximum temperature is around 40°C, a heat wave is said to occur when the day maximum remains 5°C or 6°C above the normal. In case of severe heat wave, the maximum remains higher by 7°C or more for two or more days. Places where the maximum is around 45°C are said to have heat wave conditions if such values continue to be recorded for two days or more.

The occurrence of heat wave is generally over North India; the interior parts experience it more than the coastal areas. Most parts of southern peninsula and the West Coast is free from the incidence of heat wave, as do the island regions. 17 per cent of severe heat waves occur during March months, Saurashtra and Kutch regions of Gujarat being favoured areas. The frequency decreases drastically to 7 per cent during April over extended areas of the country. There is a marginal increase in May to 10 per cent. Jammu and Kashmir is the area where the prevalence of heat wave conditions is more. Over the

plains, there is a shift from western India to eastern parts in May. The maximum frequency of 54 per cent for the occurrence of heat wave conditions is over Uttar Pradesh and adjoining areas. With the country in the grip of monsoon currents in July, the frequency drops to about 12 per cent mainly restricted to NW India especially over Punjab. A heat wave normally lasts 5-6 days. Most of the heat wave conditions originate from western Rajasthan and serially affects the eastern parts as the hot air flows eastwards. Table 8.3 shows the occasions of heat waves that the country experienced over 57 years.

Table 8.3

Total number of severe heat waves (based on data 1911 to 1967)

- Note: 1. Sub-divisions given here and in subsequent tables, correspond to those in 1965.
2. Punjab includes Delhi and Himachal Pradesh. West Bengal includes Sub-Himalayan West Bengal.
3. North Assam is excluded from this study.
4. Sub-divisions where the phenomenon was not reported at all are omitted from the table.

Cold Wave Conditions:

The period from November to March is the most favoured time when cold wave conditions prevail. When the normal minimum temperature is more than 10°C, cold wave conditions exist when the minimum temperature is less by 5 to 6°C than the normal. When this difference is higher than 7°C, a severe cold wave condition prevails. When the normal minimum temperature is lower than 10°C, a negative departure of 3-4°C from the normal brings in cold wave conditions. It is severe cold wave when the temperatures are lower by 5°C or more than the normal. A cold wave lasts normally for 4-5 days. In most cases the cold wave conditions occur after a western disturbance crosses a region.

Jammu and Kashmir is the most favoured region with 4-5 waves every year. The Indo-Gangetic plains are not much affected by this. But West Rajasthan, Gujarat, West Madhya Pradesh and Vidarbha have more frequency of occurrence of cold waves. Table 8.4 gives the number of cold waves that have occurred during a 58-year period.

Fog:

Fog is a local phenomenon, which reduces the visibility in the surrounding. Water vapour present in the atmosphere, if available in larger proportion, will condense into small water droplets when the air temperature is cooled to a temperature below its dew point. This condensation is accelerated if sufficient condensation nuclei, in the form of mineral and organic dust particles, are present in the air. The condensation can be induced by any cooling process; whether by radiation, by mixing warmer air with colder air or by the flow of warmer air over colder surfaces. In fact, cloud is also a form of fog. The fog is a condensation process very close to the soil whereas the cloud is always (generally) well separated from the soil.

The fog is classified into four types:

- (i) Radiation fog is mainly due to radiational cooling of the surface near the earth.
- (ii) Advection fog takes place when moist air is passed over a colder surface.
- (iii) Steaming fog occurs when warm water cools off by evaporation.
- (iv) Frontal fog is due to continuous rain ahead of a warm front.

Radiation fog is the more prevalent type over India, especially in the North India in winter. The conditions favourable for fog formation by radiational cooling are cloudless skies, near calm wind, high relative humidity preferably with moist soil and a stable atmospheric layer with inversion near the ground. A convergence of air at the low levels should be in the inversion layer to induce ascent of air within the inversion layer. The layer that is locked within goes on cooling to a temperature less than the dew point temperature, resulting in condensation. With sufficient condensation nuclei present, fog formation takes place. Fog cannot form if divergence is present in place of convergence due to resulting outflow. If the wind speed is significant, the wind will cause dissipation of moisture and also the mixing up of air aids uniform temperature regime. The clouds when present, prevent cooling as they return more radiant energy by reflection and by its own emission.

When warm and moist air passes over a cold surface its temperature is considerably reduced to cause dense fog. If the velocity of the warm air is large, the contact with cold

surface will be too short to effect any large-scale temperature decreases, minimising the chances for the occurrence of fogs.

Radiation fogs occur in the early hours of day and may last till noon time on occasions. The fog gets deepened in general, after sunrise as the solar heating enables the nuclei within the inversion layer to rise to provide large number of condensation nuclei for the water droplets to grow. The fog starts lifting up as the heating by solar irradiation becomes stronger, sufficient to destroy the inversion layer. The fog particles rise upwards to form low fracto stratiform clouds.

During the incidence of fog, the visibility becomes too low to become especially a navigational hazard of all types. When the preponderance of the water droplets is small, we have mist formation which does not reduce the visibility very low as it happens in the case of fog. When the condensation nuclei are of carbon origin and their density of distribution is very high, we get **smog**.

While the **mist** occurs throughout the country in winter, the occurrence of fog is generally restricted to the plains in the North, especially over Uttar Pradesh and Bihar. The fog is also widespread on many days (in winter) over Orissa, West Bengal and NE India. The Brahmaputra Basin with its abundant vegetation and water (liquid and vapour) provides an ideal zone for fog to occur. Fog occurs on as many as 20 days in a month during the winter in this area. In the wake of a western disturbance, extensive areas of the plains of North India get fog occurrence.

A p p e n d i x - I I I

REFERENCE METEOROLOGICAL YEAR - DATA

Explanatory Notes

A representative year (RY), also called typical meteorological Year (TMY) provides a standard data base, which would have frequency distributions close to the long term distribution. The data set of the RY gives the daily values of various parameters. The data are initially worked for each month using the Finkelstein-Schafer statistics utilized in the empirical methodology developed in the Sandia National Laboratory USA. The months were selected based on their statistical value which are close to the long term statistics and also on the persistency of the selected data. Thus the data selected for a month may be from a specific year and the following month's may be from yet another year. The data for each month thus selected are then catenated to form a year. Since the data thus formed are from different years for each month, a certain amount of discontinuities in the interface between the last few hours of the last day of a month and the first few hours of the first day of the succeeding month is inescapable. The discontinuity is then ameliorated by smoothing processes for the data for pressure, temperature and humidity. More details on the reference year are given in chapter VI.

The data set:

- 1) Table I gives the list of stations with their geographical coordinates and the abbreviations used in the RY tables.
- 2) RY data for Srinagar are not included as the radiation data available are too scanty.
- 3) The stations are arranged according to increasing latitude
- 4) The sequence of data presented are:
 - (i) Hourly & Daily totals of global solar radiant exposure - unit MJm^{-2}
 - (ii) Hourly & Daily totals of diffuse solar radiant exposure - unit MJm^{-2}
 - (iii) Atmospheric pressure - unit hPa
 - (iv) Atmospheric temperature - unit degree celsius.
 - (v) Atmospheric humidity - unit per cent
 - (vi) Wind speed - unit kmh^{-1}
 - (vii) Rainfall - unit mm
 - (viii) Duration of sunshine - unit hours
 - (ix) Cloud cover – unit oktas.

The use of Btu and kWh for radiant energy is no more encouraged. The okta is the unit for cloud cover with the hemispherical sky dome divided into eight parts and each part is an okta. A value of 0 okta indicates cloud free sky condition and 8 oktas stands for a completely overcast sky..

5) **Measuring the parameters:**

The measurement of a particular parameter can be made either continuously or instantaneously

- (i) Continuous measuring instruments are auto recording. They are termed autographic instruments. For use in network stations and where climatological requirements are prime concern, simplicity and convenience of operation and maintenance are important. Hence the instruments have to be of robust construction for use in rugged working conditions, even at the cost of fine resolving power, which is mostly needed only in sophisticated research studies. In India Meteorological Department, the instruments for continuous use are generally mechanical types or simpler electrical types.
- (ii) The instantaneous measurements are made using more basic instruments like mercury-in-glass barometers and mercury-in-glass thermometers. In India, these measurements are made at standard times with a specified sequence. These measurements are termed synoptic observations. Synoptic measurements are made simultaneously over a large area of the region. The observations give a broad view of a particular parameter at a particular time. They describe the current weather condition obtained at each station over a wide region at a specified time. All over the world, the synoptic observations are made at all or some of the standard times at three hourly intervals viz 00,03,06,09,12,15,18 and 21 hours U.T. The corresponding time in India Standard Time are 0530, 0830, 1130, 1430, 1730, 2030 and 2330h.

6) **Instruments used:**

Instrument	Continuous recording	Instantaneous recording
(i) Global radiant exposure	Thermoelectric pyranometer	-
(ii) Diffuse radiant exposure	Thermoelectric pyranometer with a shading device	-
(iii) Atmospheric pressure	Aneroid barograph	Mercury barometer
(iv) Atmospheric temperature	Bimetallic thermograph	Mercury thermometer
(v) Atmospheric humidity	Hair hygograph	Dry and Wet bulb mercury thermometers
(vi) winds speed	Dines pressure Tube Anemograph/electrical anemograph	Anemometer (Mechanical electrical)
(vii) Rainfall	Self recording rain gauge	Ordinary rain gauge
(viii) Duration of sunshine	Campbell – Stokes sunshine recorder	-
(ix) Cloud cover	-	Manual estimate

7) **Time frames used:**

- (i) Universal time (U.T.) is based on the mean solar time derived from the earth's rotation with respect to the sun. The reference meridian is 0° which passes through Greenwich in U.K. The synoptic measurements are always taken at specified times in U.T. This time is used for civil purpose.
- (ii) The Indian Standard Time (IST) is 5 hours and 30 minutes ahead of the universal time. The data obtained using autographic instruments are in the IST reference time.
- (iii) Local Apparent Time (LAT) is the time frame in which it is local noon when the true sun crosses the meridian of a place. In this system the durations from sun rise to local noon and from local noon to sun set are always equal. Hence the solar elevations at equidistant times with reference to this local noon are also the same and hence the data are comparable. The radiation data viz, global solar radiant exposures, diffuse solar radiation exposures and the duration of sunshine hours are given in LAT times. The LAT time frame is also known as True Solar Time (TST).

More detailed information are given in Chapter I- 'Introduction'.

8) **Entries made in the data sets:**

- (i) The hourly radiation data given at a particular hour refers to the total energy received during the preceding hour. An entry at 10 LAT gives the hourly total from 0900 h - 1000 h LAT. It is the same way in the case of sunshine data also.
- (ii) The hourly meteorological data (pressure, temperature and humidity) for a particular hour refers to the value at the middle of the hour and the previous hour. An entry at 10 IST is picked at 0930h from the chart. In the case of wind, the value represents the mean wind speed during the preceding hour (0900h-1000h) arrived at using the equal area method. The hourly rainfall data refers to the total rainfall received during the preceding hour.
- (iii) The entries at synoptic hours are obtained during a small time interval just before the hour as laid down by World Meteorological Organization.
- (iv) An entry “dash (-)” indicates that no data was available for some season. No attempt has been made to fill them up using empirical and statistical methods.
- (v) In the case of radiation data including duration of sunshine the daily total is not given, if there is a “dash (-)” even for one hour. No attempt is made to estimate the missing value by interpolation or other methods.
- (vi) (a) The clouds are classified into three groups: low, medium and high clouds. The WMO cloud Atlas gives their approximate heights as :
 - Low cloud – up to a height of 2km from surface
 - Medium cloud – 2 to 8km
 - High cloud – 6 to 18km(b) Under overcast or near overcast sky conditions, the high clouds are normally reported as “dash (-)” as they are not easily visible.
(c) The maximum amount of total cloud cover is 8. However if the cloud amount could not be estimated due to poor visibility conditions due to thick fog, smoke or haze, the total cloud cover is entered as 9.
- (vii) If for some reason, the hourly values of rainfall and sunshine are not available, then the daily totals of rainfall and sunshine are included in the tables.

- (viii) Whenever hourly data for pressure, temperature, humidity or wind are not available or very scanty for the selected reference month, synoptic data are presented. The synoptic observations may be for all eight synoptic hours or for selected hours depending on the availability of the data for this work or on the limited times of observations in vogue at the station.
- (ix) The main stress in selecting the reference month was on the low statistical score, the maximum availability of global solar radiant exposure at each station and the frequency distribution along with standard deviation of selected parameters.
